Relative to the rearrangement barrier for the uncatalyzed A/E pathway (46.9 kJ mol⁻¹), partial protonation of the migrating group with the weak gas-phase acid hydrogen fluoride (HF) reduces the barrier by 5.5 kJ mol⁻¹. The slightly stronger gas-phase acid ammonium cation NH₄⁺ reduces the barrier to 24.5 kJ mol⁻¹, while the strong gas-phase acid H₃O⁺ leads to a barrier (10.3 kJ mol⁻¹) similar to that observed with full protonation.

This systematic lowering of the rearrangement barrier can be understood in terms of the relative strength of the hydrogen bond between the acid catalyst and the migrating carbonyl oxygen in the TS versus the reactant. In effect, this interaction is stronger in the TS than that in the reactant, hence the lowering of the barrier. The trend in barriers can be rationalized in terms of the relative proton affinities of the conjugate bases of the acid catalysts and the substrate and is reflected geometrically in the distance between the acidic proton and the carbonyl oxygen of the substrate. Thus, we observe the distance between these entities to decrease across the series from infinity (no protonation) to 1.727 (HF), 1.503 (NH₄⁺), 1.046 (H₃O⁺), and 0.976 (full protonation) Å.

From an enzymatic point of view, the result obtained with NH₄⁺ is the most relevant because it provides a realistic model for amino acids such as histidine. The moderately large proton affinity of NH₃ (848.6 kJ mol⁻¹) maintains the relatively strong binding of the proton, while allowing sufficient proton transfer to the substrate to facilitate the rearrangement. Importantly, this

Figure 2 Schematic energy profiles for the rearrangement of the 3-propanal radical, showing barriers (CBS-RAD(p), kJ mol^{-1}) associated with various degrees of protonation.^{3,55} [Reprinted with permission from Ref. 3. Copyright 2010 American Chemical Society.]

Figure 3 Active-site region of MCM showing the close proximity (in Å) of His244 to the carbonyl oxygens of the substrates methylmalonyl-CoA (green) and succinyl-CoA (gray) (PDB code: 4REQ⁵⁷).

demonstrates that a significant lowering of the barrier can be achieved without full proton transfer by the enzyme.

In the context of the MCM-catalyzed reaction, the crystal structure of MCM reveals that a histidine residue (His244) lies within H-bonding distance of the migrating carbonyl oxygen of the substrate (Figure 3).⁵⁷ This arrangement potentially offers an attractive H-bond donor to mediate substrate rearrangement via partial proton transfer. On the basis of the theoretical partial-proton-transfer hypothesis,⁵⁵ Banerjee and coworkers performed mutagenesis experiments involving His244 and observed a 300-fold decrease in catalytic efficiency in experiments using an H244G mutant of MCM.⁵⁸ Other experiments with H244A and H244Q mutants

in the laboratory of Leadlay and coworkers found similar reductions in catalytic efficiency (100- to 1000-fold, respectively).⁵⁹ Overall, these combined experiments provide strong support for the involvement of His244 in the rearrangement of carbon skeletons in the MCM-catalyzed reactions. More generally, they provide support for the concept of facilitation of these rearrangements through partial proton transfer.

Despite these data, the experimental studies produced rate changes somewhat smaller than those expected on the basis of the theoretical results. While the experiments indicated an enhancement of catalytic efficiency by His244 of roughly two orders of magnitude,^{58,59} the theoretical models predict as much as four orders of magnitude. Moreover, other kinetic modeling solvation studies are not supportive of an acid-catalyzed A/E pathway.⁶⁰

In an attempt to reconcile some of these disparities, Wetmore *et al.*⁶¹ extended the original theoretical investigations to more elaborate calculations, including the first investigation of the hydrogen-abstraction reactions of MCM. Importantly, the theoretical study found that there is a change in the rate-determining step between wild-type MCM and its His244 mutants. Specifically, the rate-determining step changes from the hydrogen-atom re-abstraction (and additional, possibly coupled factors such as product release) in the wild-type enzyme to the substrate rearrangement for the His244 mutants. This change can be attributed to the loss of partial protonation from

His244 to the migrating carbonyl group. Furthermore, the use of a more sophisticated model for His244, that is, protonated imidazole, predicts that His244 would enhance the catalytic efficiency of the reaction by roughly three orders of magnitude,⁶¹ which is consistent with the two–three orders of magnitude observed experimentally. Overall, it is clear that His244 plays an important role in facilitating the radical rearrangement step in the MCM-catalyzed reaction.

2.2.3 Glutamate Mutase

GM catalyzes the reversible isomerization of (*S*)-glutamate to (2*S*, 3*S*)-3-methylaspartate (4)⁶²:

The nature of the migrating moiety (i.e., glycy) in these substrates makes it unlikely that an A/E mechanism is operative in GM, since the glycy fragment does not possess unsaturation. On the other hand, Marsh and coworkers have demonstrated that glycy radical is a kinetically competent intermediate in this reaction, suggesting that a dissociative F/R pathway may be operational.⁶³

The critical importance of the protonation state of the participating species in this reaction has been demonstrated theoretically.⁶⁴ For instance, the intermediate fragments derived from *protonated* 4-glutamyl radical are found to lie 182.5 kJ mol^{−1} higher in energy than the reactant, and the overall reaction is endothermic by 41.7 kJ mol^{−1}. For *neutral* 4-glutamyl radical, however, the energy requirements for the F/R pathway are much lower. Specifically, the barrier to fragmentation is 59.9 kJ mol^{−1}, the intermediate fragments lie 34.7 kJ mol^{−1} higher than the reactant, and the reaction endothermicity is just 20.3 kJ mol^{−1}.⁶⁴ The low energy of the separated fragments may be attributed to captodative stabilization of the glycy radical intermediate by the amino and carboxylic acid substituents adjacent to the unpaired electron.^{65–67} This stabilization is greatly reduced by protonation of the amino group.

The crystal structure of GM reveals the substrate (glutamate, Figure 4) to be bound by three

Figure 4 Selected region of the active site of GM showing the close proximities of Glu171 to the nitrogen atom of glutamate, and the so-called arginine claw to the substrate carboxylates (PDB code: 1I9C⁷⁰).

arginine residues—the so-called arginine claw—and Glu171.⁶⁸ It is evident that Glu171 is well positioned to interact and partially deprotonate the amino group of the substrate. Its role as a proton acceptor has been corroborated with mutagenesis experiments that demonstrated a 50-fold reduction in the catalytic activity of the wild-type enzyme with the Glu171Gln mutant of GM.⁶⁹

Further evidence for GM utilizing hydrogen bonding for both binding and catalysis is provided by its observed inactivation with (*S*)-2-thiolglutarate.⁷¹ Simulations of the experimental EPR spectrum for this reaction system suggested an interaction between cob(II)alamin and a sulfur-stabilized thioglycolyl radical (H[•]C(CO₂H)–SH), which would be formed via fragmentation of the C4-centered substrate-derived radical.⁷¹ The thioglycolyl radical was found to accumulate on the enzyme, and it was therefore proposed that it was too stable to undergo further reaction.

We have examined this reaction computationally and found the energy profile of neutral (*S*)-2-thiolglutaric acid to be not very different to that of another known catalytically active substrate analog (i.e., (*S*)-2-hydroxylglutarate), suggesting that some activity might have been expected to be observed.⁷² On the other hand, we find that the F/R products of the reaction involving the S-centered anion of (*S*)-2-thiolglutaric acid are of especially low energy because of effective captodative stabilization, which *would* account for the ability of this analog to inactivate GM.

In addition, an analysis of radical stabilization energies (RSEs) reveals that the thioglycolyl radical

Table 1 Comparison of calculated (G3(MP2)-RAD, 0 K kJ mol^{-1}) radical stabilization energies (RSEs) for species pertinent to the fragmentation step of the glutamate mutase reaction.⁷²

Radical	RSE
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--H}$	21.2
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--NH}_2$	94.3
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--SH}$	81.4
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--S}^{\cdot}$	126.4
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--OH}$	77.5
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--O}^{\cdot}$	83.4
$\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--F}$	43.0

($\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--SH}$) does not possess any significant stabilization that would cause the reaction to terminate prematurely (Table 1); indeed, the RSE of the thioglycolyl radical (81.4 kJ mol^{-1}) is quite similar to that of the glycolyl radical (77.5 kJ mol^{-1}). The RSE of the S-centered anion of the thioglycolyl radical ($\text{H}^{\cdot}\text{C}(\text{CO}_2\text{H})\text{--S}^{\cdot}$), on the other hand, demonstrates a significant degree of stabilization. With a calculated RSE of $126.4 \text{ kJ mol}^{-1}$, this species does indeed constitute a large energy sink for the reaction of GM with (*S*)-2-thiolglutarate. Bearing in mind the role of Glu171 as a general base in the GM-catalyzed reactions,⁶⁹ the possibility that the S-centered anion of the thioglycolyl radical contributes to the inactivation of GM with (*S*)-2-thiolglutarate as a substrate is indeed plausible. Encouragingly, calculations of the full reaction profiles for these various substrates support the notion that RSEs provide a useful qualitative measure of the ability of substrate analogs to generate kinetically competent intermediates.⁷²

2.3 Class II Eliminases

The class II eliminases differ from the class I mutases primarily in the composition of the migrating moiety; specifically, these enzymes interchange a heteroatom group such as OH or NH_2 , rather than a carbon-skeleton fragment, with hydrogen. Furthermore, and as their name suggests, elimination (of H_2O or NH_3 , depending on the enzyme) occurs following substrate rearrangement. Like the class I mutases, the mechanisms of substrate rearrangement have long been contested. Unlike the mutases, however, the eliminases are prone to substrate-induced suicide inactivation on

account of their relative promiscuity of substrate selectivity. To better understand these processes, we and others have carried out extensive theoretical modeling to delineate the dominant factors responsible for facilitating substrate rearrangement and for irreversible inactivation of these enzymes.

2.3.1 Diol Dehydratase

Diol dehydratase (DDH) catalyzes the irreversible dehydration of two-carbon and three-carbon 1,2-diols into their corresponding aldehydes (5)⁷³:

Inspired by earlier work,^{49,50} we examined the interactions of the migrating OH group with a series of Brønsted acids and found that the resulting *partial* protonation reduces the barrier for 1,2-OH migration monotonically with increasing acid strength.⁷⁴ The uncatalyzed rearrangement barrier for the 1,2-dihydroxyethyl radical was determined to be $113.1 \text{ kJ mol}^{-1}$, which was decreased substantially when the following acids were allowed to facilitate the rearrangement: protonated methylamine (76.1 kJ mol^{-1}), ammonium (49.6 kJ mol^{-1}), protonated propan-2-one (18.5 kJ mol^{-1}), and protonated methanol (2.8 kJ mol^{-1}). Full protonation resulted in a barrierless reaction. All of these examples showed a significant lengthening of the acidic bond involving H in the TS as the strength of the acid increases, with a concomitant elongation of the C–O bond of the substrate.

In a later study, the partial proton transfer concept was extended to include partial *deprotonation* of the spectator OH group.⁷⁵ As shown in Figure 5, relative to the uncatalyzed case ($110.4 \text{ kJ mol}^{-1}$, obtained with a slightly different level of theory³), partial deprotonation of the spectator OH group of the 1,2-dihydroxyethyl radical is found to reduce the barrier to rearrangement with either NH_3 ($108.1 \text{ kJ mol}^{-1}$) or HCO_2^- (94.5 kJ mol^{-1}).

If the effect of combining partial protonation and deprotonation within a system corresponded to the sum of the individual contributions, then one would expect a rearrangement barrier of

Figure 5 Schematic energy profiles for the rearrangement of the 1,2-dihydroxyethyl radical resulting from the interaction of acids (a) with the migrating OH together with the interaction of various bases (b) with the spectator OH.^{3,75} Relative energies (G3(MP2)-RAD, kJ mol^{-1}) are given in parentheses. [Reprinted with permission from Ref. 3. Copyright 2010 American Chemical Society.]

46.7 kJ mol^{-1} when NH_4^+ and NH_3 are used as the acidic and basic catalysts, respectively (Figure 5). However, this is not the case at all. In a powerful demonstration of the synergistic effect that occurs to reduce the barrier to rearrangement with the combined action of both an acid and base, we calculate a rearrangement barrier of just 7.9 kJ mol^{-1} for NH_4^+ and NH_3 . This behavior has been referred to as “push–pull” catalysis to indicate that the acidic catalyst “pushes” the migrating OH group through the 1,2-rearrangement, while the basic catalyst “pulls” it. This kind of synergism is also observed with the push–pull combination of HF and formate (Figure 5). We believe that this mechanism provides a straightforward rationalization of how DDH (and other AdoCbl-dependent enzymes) might use active-site residues to facilitate the radical rearrangement step.

The crystal structure of DDH reveals the substrate to be located near histidine (His143)

and glutamate (Glu170) residues, which are likely to serve as appropriate acidic and basic catalysts in the reaction (Figure 6).⁷⁶ Indeed, mutagenesis experiments have shown that the interaction of His143 with the substrate both assists catalysis and protects the radical intermediates from inactivation.⁷⁷ Moreover, QM/MM computational mutational investigations have demonstrated the importance of both His143 and Glu170 in the conversion of 1,2-propanediol to 1,1-propanediol.⁷⁸ The His143Ala mutant was found to increase the rearrangement barrier by $\sim 20 \text{ kJ mol}^{-1}$, while the Glu170Gln mutant increased the barrier by $\sim 25 \text{ kJ mol}^{-1}$. Disruption of partial proton transfer between these residues and the radical intermediate was identified as being the cause of these barrier increases.

Also shown in Figure 6 is a metal ion coordinating the substrate. In addition to the two coordination

Figure 6 Portion of the active site of DDH showing the substrate (*S*)-propane-1,2-diol, His143, and Glu170 and Ca^{2+} (PDB code: 1DIO⁷⁶).

positions occupied by the substrate, this ion is also coordinated by five oxygen atoms from the side chains of Gln141, Glu170, Glu221, and Gln296 and the carbonyl group of Ser362. Originally, this ion was believed to be potassium, but recent computational and experimental studies predict it instead to be calcium. Yoshizawa and coworkers used QM/MM calculations to compare metal–oxygen bond lengths for substrate binding using K^+ , Na^+ , Mg^{2+} , and Ca^{2+} as the metal.⁷⁹ It was found that Ca^{2+} gives the best agreement with experiment for the seven metal–oxygen bond distances. In addition, the best agreement with the experimental X-ray structure for the adenine-binding site is found for K^+ , which rationalizes experimental evidence indicating that K^+ plays an essential role in the binding of AdoCbl with DDH. Collectively, these results suggest that the metal ions in the substrate- and adenine-binding sites are Ca^{2+} and K^+ , respectively. Subsequent experiments supported this interpretation.⁸⁰

Another aspect of the DDH-catalyzed reaction is its susceptibility to irreversible inactivation with substrate analogs. Glycolaldehyde has long been known to lead to the inactivation of DDH,⁸¹ and more recently, the causative agent for this inactivation has been proposed on the basis of EPR experiments to be the *cis*-ethanesemidione radical.⁸² It was argued that this species is too stable to allow the reaction to proceed further. Likewise, the substrate analog chloroacetaldehyde was found to elicit a similar outcome. Subsequent

computational investigations determined that the inactivation was indeed due to the intervention of a very stable species. However, it was found that it is not the *cis*-ethanesemidione radical, because the latter is actually a TS connecting a pair of equivalent glycolaldehyde radicals that lie 38.0 kJ mol^{-1} lower in energy. Rather, the very stable species involved in the reaction is in fact glycolaldehyde radical, which can be generated from both glycolaldehyde and chloroacetaldehyde.⁸³ Thus, the suicide inactivation appears to be a consequence of the inability of the glycolaldehyde radical to re-abtract an H atom from Ado–H to generate the final product and regenerate Ado[•] (step C of Scheme 1). Indeed, the barrier and reaction enthalpy for this process are calculated to be >110 and $+85 \text{ kJ mol}^{-1}$, respectively. Such energy requirements are likely to be too demanding for the enzyme to overcome under physiological conditions.

Subsequent computational investigations highlighted several additional instances of similar termination mechanisms to be operational in the reactions catalyzed by DDH with various other substrate analogs, including ethane- and propane-triols, glyceraldehyde, and glyoxal.⁸⁴ In each case, the catalytic cycle is terminated prematurely because a very stable radical intermediate prevents the H-atom re-abstraction step from Ado–H from occurring.

2.3.2 Glycerol Dehydratase

An enzyme that shares striking similarities with DDH is glycerol dehydratase (GDH).⁸⁵ Like DDH, GDH catalyzes a 1,2-OH shift and dehydration of its substrate. In this case, glycerol is converted to 3-hydroxypropionaldehyde plus water (6):

Because glycerol is available in good supply as a byproduct in the biofuel industry, there is currently significant interest in exploiting this reaction to convert glycerol to valuable feedstock chemicals.

Recently, GDH has been observed to undergo time-dependent inhibition with the substrate

analog but-3-ene-1,2-diol (**6a**).⁸⁶ EPR studies, in combination with deuterium labeling at C1, C2, and C4 of **6a**, indicate spin density to be located at C1, suggesting the presence of the 1,2-dihydroxybut-3-en-1-yl radical (**7a**), which would be formed directly via an initial H-atom abstraction from C1 of **6a** (7):

Separate studies involving reaction of the related enzyme DDH with 3-unsaturated 1,2-diols, which included **6a** as well as but-3-yne-1,2-diol (**6b**, (7)), have demonstrated that these reactions also terminate prematurely.⁸⁷

We have compared the reaction profiles involving the reaction of GDH with glycerol and with the substrate analogs **6a** and **6b** to investigate these phenomena.⁸⁸ Our calculations indicate that the energy requirements for the catalytic pathway for GDH with glycerol are very similar to those obtained for DDH (Section 2.3.1). In addition, our calculations indicate that the initial radicals **7a** and **7b** produced from the substrate analogs **6a** and **6b** can rearrange to **8a** and **8b** with exothermicities of 83.4 and 67.5 kJ mol⁻¹, respectively, consistent with expectations based on the stabilizing effect of vinyl or ethynyl substituents adjacent to the radical center in the latter. Furthermore, the barrier to generate **8a** from **7a** is calculated to be 94.3 kJ mol⁻¹, which is lower than that calculated for glycerol (116.8 kJ mol⁻¹), and likely to be lowered further through partial proton transfer to/from the migrating and spectator OH groups. It thus appears quite likely on energy grounds that GDH has the capacity to transform the initially formed radicals in these substrate analogs (**7**) to their rearranged products (**8**). It is therefore curious that isotopic labeling studies involving GDH and **6a** suggest the presence of **7a**. Further experiments are desirable in order to help understand why the transformation of **7a** to **8a** appears not to take place, particularly given that both GDH and DDH exhibit similar inactivation outcomes.

2.3.3 Ethanolamine Ammonia-Lyase

Ethanolamine ammonia-lyase (EAL) catalyzes the irreversible deamination of (protonated) 2-aminoethanol (R = H) to acetaldehyde plus ammonium cation and (protonated) 2-amino-3-propanol (R = CH₃) to propionaldehyde plus

ammonium cation (8)⁷³:

As found with DDH and GDH, the ability of EAL to tolerate substrate modifications has led to a set of diverse and interesting side reactions. As in DDH, glycolaldehyde was found to inactivate EAL and to give an EPR spectrum that parallels that observed with DDH⁸²; the inactivation is therefore likely to again be caused by the highly stabilized glycolaldehyde radical.⁸⁹ Reed and coworkers have established that the substrate analog 2-hydroxyethylhydrazine (HEH) also causes the rapid, irreversible inactivation of EAL, with acetaldehyde and the hydrazinium radical cation identified as products.^{90,91} Interestingly, the energy requirements for the reaction of HEH were found to be very similar to those calculated for (8) with the native substrate, suggesting that in the absence of another pathway, HEH ought to be a catalytically viable substrate analog.⁸⁹ However, a lower energy pathway involving the hydrazinium radical cation exists, which may in principle occur from either the substrate-derived or product-related radicals; quite possibly, it occurs during a failed 1,2-migration event. Like the glycolaldehyde radical, the hydrazinium radical cation is apparently too stable to permit the necessary H-atom re-abstraction step, thus terminating the catalytic cycle.⁸⁹

In yet another situation involving irreversible inactivation, 2-aminoacetaldehyde was found to elicit inactivation of EAL, with acetic acid and 4',5'-anhydroadenosine as major products from the reaction as well as degradation of the corrinoid cofactor.⁹² On the basis of similar energy requirements for the EAL-catalyzed reaction of (protonated) 2-aminoethanol, our calculations provide evidence that (protonated) 2-aminoacetaldehyde can generate acetic acid, though they do not easily account for the formation of 4',5'-anhydroadenosine. It was suggested that the presence of an unbound carboxylate, as might be made available from acetic acid, may participate in the subsequent oxidation of 5'-deoxyadenosyl radical to yield this unusual product.⁸⁹

Another important aspect of interest in the EAL-catalyzed reaction involves the mechanism of radical rearrangement. The generally accepted mechanism for the 1,2-shift of the (protonated) amino group in the substrate-derived radical to form a product-related radical is a direct migration pathway (cf. Scheme 1, step B). In principle, it is also possible that NH_4^+ dissociates from the substrate-derived radical to give a vinyloxy radical, which could generate acetaldehyde directly via re-abstraction of an H atom from Ado-H. However, calculations indicate this direct elimination route to be less likely because it would require a high-energy re-abstraction of an unactivated H atom from Ado-H by the stabilized vinyloxy radical.^{93,94}

The energy requirements for the intramolecular 1,2-shift (cf. pathway F, Scheme 2) have also been examined. The barrier for this transformation in protonated 2-amino-1-hydroxyethyl radical is found to be 65.8 kJ mol^{-1} ,⁹³ which is consistent with the experimental reaction rate. Interestingly, the result of either full or partial deprotonation of the amino group serves to increase the barrier to rearrangement. At the extreme, full deprotonation was found to yield a fragmentation barrier some 30.7 kJ mol^{-1} higher in energy (at 96.5 kJ mol^{-1}) than its protonated counterpart. In another related study, the use of imidazole to partially deprotonate the amino group in protonated 2-amino-1-hydroxyethyl radical leads to a rearrangement barrier of $114.6 \text{ kJ mol}^{-1}$.⁹⁴ Taken together, these results suggest that full protonation of the migrating group results in the most efficient rearrangement of the substrate and that any deprotonation is likely to be anti-catalytic. However,

since H-bonding within the active site of EAL is likely to result in at least some partial deprotonation of the amino group of (protonated) aminoethanol, EAL must use an additional strategy to facilitate catalysis.

Apparently, this strategy takes the form of partial deprotonation of the spectator OH group of aminoethanol, which plays a crucial role in lowering the rearrangement barrier in this reaction. Indeed, we find that the rearrangement barrier for neutral 2-amino-1-hydroxyethyl radical (96.5 kJ mol^{-1}) is reduced by 1.8, 18.2, and 33.8 kJ mol^{-1} , respectively, when NH_3 , CN^- , and OH^- interact with the spectator OH group. In the limit of full deprotonation, the barrier to fragmentation is just 29.5 kJ mol^{-1} .⁹³ Similar findings were reported by Semialjac and Schwarz.⁹⁴

Perhaps the most striking conclusion from these studies is that a combination of "push-pull" catalysts constitutes the most plausible mechanism for the EAL-catalyzed rearrangements. In this scenario, the protonated migrating group and the OH spectator groups are bound by basic catalysts, which significantly reduce the barrier to rearrangement. As an example, consider the results for neutral 2-amino-1-hydroxyethyl radical, which possesses a rearrangement barrier of 96.5 kJ mol^{-1} in the absence of any catalysts.⁹³ A small increase (of 2.6 kJ mol^{-1}) in the rearrangement barrier is observed for the interaction of NH_4^+ at the migrating NH_2 group, while a very small lowering in the barrier (of -1.8 kJ mol^{-1}) is observed if NH_3 interacts with the spectator OH group. However, the combination of both of these interactions reduces the barrier to 66.0 kJ mol^{-1} . Analogous synergistic benefits of this type have also been observed using imidazole and acetate.⁹⁴ In this case, the catalyzed rearrangement barrier is 57.3 kJ mol^{-1} . Both results are consistent with experimental rate data and provide an attractive mechanism for the EAL-catalyzed reaction.

Very recently, X-ray crystal structures of an N-terminal truncation of the *Escherichia coli* EAL β -subunit have been obtained in the presence and absence of the substrate.⁹⁵ The substrates are bound by six H-bonds involving Arg160, Gln162, Asn193, Glu287, and Asp362. With 2-amino-1-propanol as substrate, both Arg160 and Glu287 are found to be within H-bonding distance of O1 of the substrate (2.71 and $2.80 \text{ \AA}$, respectively). The oxygen of Gln162 is $2.80 \text{ \AA}$ from the migrating N atom of

the substrate. It is interesting to note that the position of Arg160 in the crystal structure of EAL corresponds to the metal ion position in both diol and glycerol dehydratases,⁹⁵ suggesting that its role may, at the very least, serve to correctly position the substrate for its subsequent rearrangement. Of relevance here are mutagenesis experiments that have revealed a critical role for Arg160 in the EAL-catalyzed reactions.⁹⁶ Glu287 almost certainly serves to partially deprotonate the O1 hydroxyl group, while the position of Gln162 is consistent with a weak conjugate base interacting with an almost fully protonated migrating N atom. Now that an EAL crystal structure is available, future computational modeling studies will be of interest in order to further examine the role of the partial proton transfer concept in the EAL-catalyzed reaction.

2.4 Class III Aminomutases

The third and final class of AdoCbl-dependent enzymes that we have examined corresponds to the aminomutases. These enzymes catalyze the reversible 1,2-amino shift in certain amino acids for their subsequent cleavage into easily metabolized intermediates.²⁷ Members from this class include lysine-5,6-aminomutase (5,6-LAM) and ornithine-4,5-aminomutase. In addition to their requirement for AdoCbl, these enzymes also require pyridoxal-5'-phosphate (PLP), a derivative of vitamin B₆, for activity. PLP is believed to form an imine linkage to the migrating group of the substrate, thereby facilitating catalysis.

Despite the additional requirement of PLP, these reactions are proposed to be closely related to those of the other AdoCbl-dependent enzymes. The rearrangement step is thought to proceed via an intramolecular A/E pathway involving an azacyclopropylcarbinyl radical (I') intermediate (9) (see also pathway G, Scheme 2):

We note that of all the AdoCbl-dependent enzymes, the aminomutases are likely to be the only class to possess discrete intermediates during the rearrangement step. For example, GM proceeds via a F/R mechanism, while the substrate rearrangement in MCM is likely to proceed in a single direct step.

In any event, uncertainties concerning the rearrangement mechanism for the aminomutases prompted us to investigate the role of PLP and how it might facilitate the 1,2-NH₂ shifts. First, we examined the energy requirements for a 1,2-NH₂ shift in the absence of PLP. Using 2-aminoethyl radical as our simplest model, we found a rearrangement barrier of 90.5 kJ mol⁻¹. Interestingly, protonation of the amino group was found to increase the barrier to 104.8 kJ mol⁻¹.⁹⁷

Next, we examined models including the essential features of PLP in order to examine its effect on the energy requirements for rearrangement. In principle, the imine linkage formed between PLP and the migrating group of the substrate can permit an intramolecular rearrangement pathway. Furthermore, the OH group could also lower the energy requirements through its action as an intramolecular H-bond donor. To examine the effect that the imine may have on the rearrangement barrier, 2-(*N*-methylidene)ethyl radical was initially used. In this case, the barrier for ring closure to generate the cyclic 1-aziridinylcarbinyl radical is 76.2 kJ mol⁻¹ and the reaction is endothermic by 42.2 kJ mol⁻¹ (Figure 7). The barrier to ring closure is found to decrease further (to 61.3 kJ mol⁻¹) when models incorporating the added functionality of the pyridoxal moiety are used (as in S', (9)). The barrier is reduced to 37.2 kJ mol⁻¹ on protonation at the pyridine nitrogen, and the cyclic intermediate is stabilized considerably (Figure 7).

These calculations reveal two critical roles for PLP in the facilitation of the 1,2-NH₂ shifts. The first role is to introduce unsaturation into the substrate via the aldimine linkage, which lowers the energy of the radical intermediates via an intramolecular pathway. The second important role of PLP is to stabilize high-energy intermediates, for example, the aziridinylcarbinyl radical, through the cooperation of electron donation (by the C–N bonds) to the radical center and π -electron withdrawal from the radical center (by the pyridoxal ring). In addition, this is enhanced with protonation of the pyridoxal ring.

Figure 7 Schematic energy profiles (RMP2/G3MP2Large, kJ mol^{-1}) for the degenerate rearrangement of substituted 2-(*N*-methylidene)ethyl radicals.^{3,97} [Reprinted with permission from Ref. 3. Copyright 2010 American Chemical Society.]

Much of what has been learned in these reactions has been obtained through experiments with 2,3-LAM.⁹⁸ This enzyme is similar to 5,6-LAM in that it catalyzes a 1,2- NH_2 shift. However, instead of using AdoCbl to initiate substrate catalysis via Ado $^{\bullet}$, 2,3-LAM generates Ado $^{\bullet}$ via reductive cleavage of the C–S bond of *S*-adenosylmethionine (AdoMet or SAM) by a 4Fe4S cluster. Both the P $^{\bullet}$ and S $^{\bullet}$ intermediates have been identified via EPR spectroscopy for the 2,3-LAM-catalyzed reaction. However, detection of the putative cyclic intermediate (I $^{\bullet}$) remains elusive.

We have sought to remedy this situation by examining energy profiles of model substrates and their analogs. Importantly, substitution with π -acceptors of increasing strength at the exocyclic carbon is found to stabilize I $^{\bullet}$ to an extent that experimental verification, especially in the reactions catalyzed by 5,6-LAM, may be possible.⁹⁹ For example, Figure 8 shows that the π -acceptors $\text{Z} = \text{C}\equiv\text{CH}$ and $\text{CH}=\text{CH}_2$ are able to stabilize I $^{\bullet}$ by 30–40 kJ mol^{-1} relative to the unsubstituted system. It is presently unclear whether the enzymes can tolerate such changes in the substrate. However, strategies such as these may enable the first experimental characterization of an I $^{\bullet}$ -like structure in the aminomutase-catalyzed reactions.

3 GLYCYL RADICAL ENZYMES

The enzymes in the second group that we examine are known to utilize a peptide backbone glycy radical in their reaction mechanism. These so-called glycy radical enzymes require post-translational activation by specific iron–sulfur proteins¹⁰⁰ that belong to the *S*-adenosylmethionine (SAM) radical enzyme superfamily.^{101,102}

3.1 Pyruvate Formate Lyase

Pyruvate formate lyase (PFL) is an enzyme found in *E. coli* and other microorganisms that catalyzes the coenzyme A (CoA)-dependent reversible cleavage of pyruvate into acetyl-CoA plus formate during anaerobic glucose metabolism.¹⁰³ The transformation proceeds via a stepwise transfer of an acetyl group, firstly from pyruvate to an enzyme-bound cysteine residue (ES–H) and then from the acetylated enzyme (ES–acetyl) to CoA (10) and (11):

Figure 8 Relative energies of S[•], I[•], and P[•] for various Z-modified PLP derivatives pertinent to the 2,3-LAM-(X = CO₂H) and 5,6-LAM-(X = H) catalyzed reactions.⁹⁹

The active form of PFL contains a backbone glycyl radical (Gly734)¹⁰⁴ that is generated by the stereospecific abstraction of its C-2 *pro-S* H atom via a specific activating enzyme called *PFL activase*.¹⁰⁵ In addition to Gly734, two cysteines (Cys418 and Cys419) are required for catalysis.¹⁰⁶ Figure 9 shows the active site of PFL, including two arginines (Arg176 and Arg435) that bind and position the substrate via salt bridges.¹⁰⁷

The currently accepted mechanism for PFL catalysis was first proposed in 1999 by Knappe and coworkers¹⁰⁸ and developed with insights from theoretical calculations¹⁰⁹ based on an earlier mechanistic proposal (Scheme 3).¹¹⁰ Following activation to generate the glycyl radical at Gly734, the radical center is shuttled to Cys418 via Cys419 (steps a and b, Scheme 3). The Cys418 cysteinyl radical then attacks the carbonyl carbon (C2) of pyruvate to generate a tetrahedral oxy-radical intermediate (step c), which fragments to CO₂^{•-} and acetylated Cys418 (step d). CO₂^{•-} then abstracts an H atom from Cys419 (step e), which in turn

Figure 9 Crystal structure of the active site of PFL (PDB code: 1H16¹⁰⁷).

abstracts an H atom from CoA-SH to generate CoA-S[•] (step f). Finally, condensation of the acetyl group bound to Cys418 with CoA-S[•] generates acetyl-CoA plus a Cys418 radical (step g). The

Scheme 3 Currently accepted mechanism for the PFL-catalyzed reaction.¹⁰⁸

mechanism is interesting because, in contrast to the coenzyme B₁₂-dependent reactions, the substrate is activated by radical addition rather than H-atom abstraction.

Himo and Eriksson¹⁰⁹ were the first to investigate the complete PFL-catalyzed reaction using small-model calculations in combination with the B3-LYP/6-311+G(2 d,2p) level of theory. Their model used the methyl thiyl radical to represent the protein-bound cysteinyl radical, which was justified on the basis of comparable S–H bond dissociation energies, and protonated pyruvate as the substrate. Protonation of the substrate was assumed on account of the active-site arginine residues that would likely neutralize the substrate carboxylate. In order to accurately describe the expected π -electron delocalization in the backbone glycyl radical,⁶⁵ an extended CHO–NH–CH₂–CO–NH₂ fragment was used as a model for glycine.

The barrier for H-atom transfer between cysteine and the glycyl radical (step a, Scheme 3) was calculated to be 41.4 kJ mol^{−1} and the reaction was found to be endothermic by 14.2 kJ mol^{−1}. The reaction energy highlights the differential thermodynamic stabilization of the glycyl radical compared with the thiyl radical, which is relevant for all glycyl radical enzymes. Despite the endothermicity, the calculations suggest that the proposed cysteine activation is feasible, both for PFL and in the general case.

The next phase of the PFL-catalyzed reaction involves the formation and the collapse of the tetrahedral radical intermediate (steps c and d, Scheme 3). The requisite addition of the thiyl radical to the carbonyl carbon of pyruvate (step c) has a calculated barrier of 51.5 kJ mol^{−1} and an endothermicity of ~40 kJ mol^{−1}. Dissociation of the intermediate into acetylated cysteine and [•]CO₂H (step d) is associated with a barrier of 11.7 kJ mol^{−1} and an exothermicity of 16.3 kJ mol^{−1}. The acetyl transfer from pyruvate to the methyl thiyl radical was calculated to be endothermic by 25.1 kJ mol^{−1}. These relatively moderate energy requirements suggest that, in the case of PFL, substrate activation by radical addition, as opposed to H-atom transfer, is indeed reasonable.

The quenching of [•]CO₂H by the model for cysteine (Cys419, step e, Scheme 3) was found to possess a barrier of just 4.6 kJ mol^{−1} with an exothermicity of 60.0 kJ mol^{−1}, which appears sufficient to compensate for the previously outlined endothermic steps. It was noted that a direct H-atom transfer could in principle occur between Gly734 and [•]CO₂H. However, the higher barrier (of 20.5 kJ mol^{−1}) and larger distance associated with the glycine suggested this to be unfavorable. The barrier for the H-atom transfer involving Cys419 and CoA–SH (step f) is calculated to have a barrier of 10.0 kJ mol^{−1} and, on account of the models used, is thermoneutral. The transfer of the acetyl group between Cys418 and CoA–S[•] (step g) has

a calculated barrier of 48.5 kJ mol^{-1} . Finally, the regeneration of the glycyl radical involves H-atom transfer to the cysteinyl radical (the reverse of step a, Scheme 3), with a barrier of 27.2 kJ mol^{-1} and an exothermicity of 14.2 kJ mol^{-1} . The net conversion of pyruvic acid plus methane thiol to formic acid plus the thioester is exothermic by 33.8 kJ mol^{-1} .

Overall, the calculations of Himo and Eriksson demonstrate that the mechanism shown in Scheme 3 is, in principle, feasible. Indeed, this theoretical study, which was performed before the resolution of the X-ray crystal structure of PFL, was instrumental in discriminating between varying mechanisms that had been proposed in the literature.

Following the release of the X-ray crystal structure, the PFL-catalyzed reaction was re-examined using similar theoretical protocols (i.e., B3-LYP/6-311++G(3df,3pd)) but with slightly different chemical models.¹¹¹ While Gly734 was again modeled with $\text{CHO-NH-CH}_2\text{-CO-NH}_2$, the cysteine model was extended to include the neighboring cysteine side chains and the associated peptide backbone. Anionic forms of the substrate pyruvate and the reaction product formate were used. The justification for this choice was primarily based on the likely protonation state of pyruvate under physiological conditions (pK_a is 2.5).

The principal difference arising from the use of the anionic pyruvate is the prediction of a concerted mechanism for the addition of the thiyl radical to pyruvate and the elimination of $\text{CO}_2^{\cdot-}$ (steps c and d, Scheme 3). In other words, in contrast to the neutral pyruvic acid, there is no evidence for a tetrahedral intermediate in the anionic case. The barrier for this step is calculated to be 49.4 kJ mol^{-1} using the large cysteine model, with an endothermicity of 32.6 kJ mol^{-1} . The product complex shows the leaving $\text{CO}_2^{\cdot-}$ group to be in close contact with the acetyl-cysteine moiety (C–C bond distance of $2.03 \text{ \AA}$). Moreover, a significant degree of electron spin (0.53) remains on the acetyl-cysteine moiety, suggesting that further dissociation of $\text{CO}_2^{\cdot-}$ will further lower the energy of the product complex. As in the previous study,¹⁰⁹ H-atom transfers from either Gly or Cys to $\text{CO}_2^{\cdot-}$ species were investigated. Using $\text{CO}_2^{\cdot-}$ leads to smaller H-atom abstraction barriers than when $\cdot\text{CO}_2\text{H}$ is used, but the preference for H-atom abstraction involving Cys419 is maintained.

Following this study, Guo and Himo¹¹² re-investigated the PFL-catalyzed reaction using an extended model. Selected atoms of the included amino acid residues were frozen to their X-ray coordinate values in a so-called “frame model” in order to mimic the enzyme structure. Two positively charged arginine side chains were included in the model in order to bind the negatively charged pyruvate. This model was considered to be superior to both the fully neutral¹⁰⁹ and anionic¹¹¹ pyruvate models used earlier.

The X-ray structure of PFL shows Gly734 to be located within a loop. The use of a frame model is found to constrain the geometry of the glycyl radical such that it cannot adopt its preferred planar conformation. Relative to the ideal geometry, the BDE is 33.9 kJ mol^{-1} higher for the constrained glycine model, which translates into an exothermicity of 19.2 kJ mol^{-1} for the H-atom-transfer step between Cys419 and Gly734. Although this result contradicts EPR experiments, which identify a stable glycyl radical, it is argued that the activation of PFL permits the loop containing the glycyl radical to open to accommodate a more favorable glycyl radical geometry.¹¹²

In contrast to the mechanism with an isolated anionic pyruvate, the frame model predicts a step-wise transfer of the acetyl group from pyruvate to cysteine (steps c and d, Scheme 3).¹¹² Instead of a single tetrahedral intermediate in this process, however, Guo and Himo located two shallow intermediates separated by a small barrier. The second of these, which precedes the C–C bond cleavage, was similar in its relative energy, structure, and spin characteristics to the one obtained by Lucas *et al.*¹¹¹ Another difference arising from the use of the frame model was the proposal that the $\text{CO}_2^{\cdot-}$ abstracts an H atom from CoA-SH rather than from Cys419. This proposal is based on observations that indicate H-atom transfer from Cys419 to the C atom of the $\text{CO}_2^{\cdot-}$ to be difficult on structural grounds.¹¹²

More recently, Smith and coworkers have used the PFL-catalyzed reaction as a prototypical radical-enzyme-catalyzed reaction in order to determine the most appropriate manner with which to truncate an arginine-bound carboxylate motif in small-model studies.¹¹³ The focus of this study was on the acetyl transfer from pyruvate to the cysteine (steps c and d, Scheme 3). Therefore, only the substrate and methanethiyl radical were considered.

The *syn* orientation of the carboxylic acid proton of (neutral) pyruvic acid was chosen over the lower energy *anti* orientation used earlier, since it was argued that an intramolecular H-bond (i.e., *anti*) is unlikely to be present in the active site of the enzyme, especially when an arginine residue lies close to the carboxylate group.

With the *syn* pyruvic acid model, two shallow minima were found for the acetyl-transfer step, in agreement with the frame-model study of Guo and Himo.¹¹² The results obtained with B3-LYP/6-31G(d) were found to overestimate those obtained with the high-level G3(MP2)-RAD procedure, by 10–20 kJ mol⁻¹, whereas the use of the larger G3MP2Large basis set with B3-LYP slightly improved the agreement with the higher-level approach.¹¹³

With anionic pyruvate, the thiyl radical addition to the substrate was predicted to be concerted,¹¹³ in agreement with a previous study using a similar model.¹¹¹ However, the reaction was found to be exothermic with higher levels of theory, which, in contrast to the previous results, implies that the anionic pathway may not benefit energetically from reacting further.¹¹³

This study went on to compare the small-model results of neutral/anionic pyruvate with those obtained with the zwitterionic complex of anionic pyruvate with an adjacent protonated methylguanidinium, where the latter ion was used as a model for arginine.¹¹³ Overall, this model more closely resembles the results obtained using neutral pyruvic acid than anionic pyruvate and gives results in very good agreement with those obtained previously using a much larger model. On this basis, it was suggested that, when the inclusion of species such as the methylguanidinium ion is not practical, neutral (*syn*) carboxylic acids provide a much more realistic treatment of an arginine-bound carboxylate motif than the bare anionic form.

Smith and coworkers also used the PFL-catalyzed reaction to develop a compound QM/MM procedure called ONIOM(G3(MP2)-RAD:MM),¹¹⁴ which is based on the multilayered ONIOM method of

Morokuma and coworkers.¹¹⁵ In their QM/MM division, pyruvate was placed in the QM region, while the methylguanidinium ion was treated with an MM description. The resulting ONIOM(G3(MP2)-RAD:MM) results were assessed against pure QM G3(MP2)-RAD results to determine the viability of using high-level QM treatments in the QM/MM formalism.

Interestingly, similar results for the radical addition to pyruvate were obtained regardless of whether the methylguanidinium fragment was treated classically or quantum mechanically. Both methods give two intermediates and three TSs. Despite some minor discrepancies, which appear to be the result of charge transfer from pyruvate to the methylguanidinium, the ONIOM(G3(MP2)-RAD:MM) procedure was found to provide a reliable high-level QM/MM treatment for enzyme-catalyzed reactions.

In addition to the methodological aspects, this study addressed the inhibitory effect of oxamate and an alternative mechanism involving activation by H-atom abstraction.¹¹⁴ Oxamate was found to exhibit a significantly higher barrier for thiyl radical addition than the substrate pyruvate. Although H abstraction of the substrate was found to be energetically competitive with radical addition, the former pathway is not productive and hence not expected to be observed.

3.2 Benzylsuccinate Synthase

Benzylsuccinate synthase (BSS) is an enzyme that is involved in the anaerobic toluene degradation that occurs in denitrifying and sulfate-reducing bacteria such as *Thauera aromatica* and *Desulfobacula toluolica*.^{116,117} The discovery that these bacteria survive on toluene and related aromatic compounds as their sole source of carbon and energy has generated significant interest for the possible use of BSS in bioremediation strategies.¹¹⁸ BSS catalyzes the addition of toluene to fumarate to produce (*R*)-benzylsuccinate (12)¹¹⁹:

Scheme 4 Proposed mechanism for the benzy succinate synthase-catalyzed reaction.^{120,121}

The proposed mechanism for the reaction catalyzed by BSS is shown in Scheme 4.^{120,121} Catalysis is initiated by the activation of BSS to form a glycy radical (Gly828).¹²¹ This radical is transferred to an active-site cysteine (Cys492) (step a, Scheme 4) which, in the forward direction as shown in Scheme 4, is likely to be rate limiting.¹²² In line with the vast majority of radical enzymes, the substrate is activated by H-atom abstraction. In this case, Cys492 abstracts an H atom from toluene to generate a benzyl radical (step b). Addition of the benzyl radical to the double bond of fumarate generates a benzy succinyl radical (step c),¹²³ which then abstracts an H atom from cysteine (step d). At this stage, the cysteinyl radical either abstracts an H atom from Gly828 to regenerate the starting state (step e) or initiates the next catalytic cycle with another H-atom abstraction from another toluene substrate.

Despite the fact that a crystal structure of BSS is not yet available, theoretical calculations can still provide important insights into the thermodynamic and kinetic feasibility of the proposed mechanism. Using models for the substrate and active-site glycine and cysteine residues, Himo¹²⁴

examined the proposed catalytic cycle of BSS using DFT. Consistent with the PFL results, the first H-atom-transfer step from cysteine to the glycy radical (step a, Scheme 4) is calculated to possess a barrier of 44.8 kJ mol^{-1} in a reaction that is slightly endothermic (by 14.2 kJ mol^{-1}).¹²⁵ The subsequent H-atom abstraction from the methyl group of toluene (step b) is calculated to have a barrier of 39.7 kJ mol^{-1} with a reaction energy of $+13.0 \text{ kJ mol}^{-1}$. It was pointed out that the overall endothermicity (of 27.2 kJ mol^{-1}) for these first two H-atom transfers is consistent with a constant EPR spectrum of BSS in the presence of toluene but not fumarate.¹²¹ The attack of the benzyl radical on the double bond of fumarate to generate the benzy succinyl radical intermediate (step c) has a barrier of 62.8 kJ mol^{-1} and an exothermicity of 42.3 kJ mol^{-1} . This step can be considered to be analogous to the recombination step of the F/R mechanism for the previously mentioned class I mutases (Section 2.2). H-atom transfer from the thiol to the benzy succinyl radical intermediate (step d) is exothermic by 24.3 kJ mol^{-1} with a barrier of 29.3 kJ mol^{-1} . Finally, H-atom transfer from Gly to the cysteinyl

radical (step e), which is calculated to possess a barrier and exothermicity of 30.5 and 14.2 kJ mol⁻¹, respectively, regenerates the initiating glycyl radical.

In the absence of structural information as to the positions of the Cys and Gly residues in the BSS active site, a direct H-atom transfer from glycine to the benzylsuccinyl radical intermediate was also considered. In this case, the barrier and exothermicity are calculated to be 73.2 and 38.5 kJ mol⁻¹. This barrier is significantly higher than that for H-atom transfer from Cys to the benzylsuccinyl radical intermediate (24.3 kJ mol⁻¹) and suggests that on an energy basis alone, the pathway shown in Scheme 4 is preferred.

4 RIBONUCLEOTIDE REDUCTASE

Ribonucleotide reductases (RNRs) are enzymes that convert ribonucleotides to 2'-deoxynucleotides and are therefore critical for both the synthesis and repair of DNA (13)^{126,127}:

RNRs have been divided into three main classes that differ with respect to the composition of the metal cofactors used to initiate radical generation. Briefly, class I RNR enzymes are found throughout eukaryotes as well as some prokaryotes and viruses and rely on iron and oxygen to generate a tyrosyl radical. We will not review the theoretical studies of this class of RNRs and instead the reader is referred elsewhere for comprehensive reviews on this topic.^{18,128,129} Class II RNRs are found in aerobic and anaerobic bacteria and utilize coenzyme B₁₂ to interact directly with an active-site cysteine residue to form the reactive cysteinyl radical required for ribonucleotide reduction. These will not be reviewed either.

The third class of RNRs, which we will cover in this section, are class III RNRs, which are

found in strict or facultative anaerobic bacteria and some bacteriophages. The formation of radicals is initiated by one-electron reductive cleavage of *S*-adenosylmethionine (SAM) by a 4Fe4S cluster to generate the 5'-deoxyadenosyl radical (Ado[•]) plus methionine. Ado[•] then goes on to abstract an H atom from glycine to form the glycyl radical, which abstracts an H atom from cysteine to generate the reactive cysteinyl radical. Formate is another cofactor required for class III RNRs and is suggested to be a precursor of CO₂^{•-}, which serves as a reductant for the 3'-keto group of a reaction intermediate, a role that is served by two cysteine residues in the aerobic enzymes. Strictly speaking, class III RNRs may be classified as glycyl radical enzymes since they are activated in the same manner. Here, however, we differentiate them from PFL and BSS of Section 3 to highlight their distinct importance and their relationship with class I and II RNRs.

Siegbahn and coworkers have investigated the class III RNR reaction using DFT, with formic acid as a cofactor that catalyzes the loss of water from the substrate (Scheme 5).^{130,131} Their preliminary

small-model investigation focused on the role of formic acid in the uniquely anaerobic transfer of the radical center from Cys79 to C3' of the substrate with the concomitant formation of CO₂.¹³⁰ It was assumed that the initial stages of the substrate transformation in class III RNRs were largely the same as those obtained earlier for the corresponding aerobic enzymes (these are analogous to steps a–e, shown in Scheme 5). Starting from the 3'-keto form of the substrate and the cysteinyl radical at position 79 (cf. step f, Scheme 5), the barrier for H-atom abstraction by Cys79[•] from the carbon atom of formic acid was calculated to be 59.4 kJ mol⁻¹ and the reaction found to be endothermic by 40.6 kJ mol⁻¹. The high relative energy of the resultant [•]CO₂H species indicates that it is likely to be a very short-lived entity, which was suggested

Scheme 5 Complete reaction mechanism of class III RNR studied by Cho *et al.*¹³¹

to help explain why aberrant side reactions do not occur in class III RNRs. It was also suggested that the energetic cost (of $\sim 40 \text{ kJ mol}^{-1}$) for $\cdot\text{CO}_2\text{H}$ to break its strong H-bond with the substrate is not easily compensated for.¹³⁰

The $\cdot\text{CO}_2\text{H}$ intermediate was then proposed to transfer its hydroxyl H atom to the carbonyl oxygen of the 3'-keto-deoxyribose ring to give CO_2 and a 2'-deoxyribose-related radical (cf. step g, Scheme 5). This step has the attractive feature that the reduction of the substrate keto group can occur without the direct involvement of $\text{CO}_2^{\cdot-}$. This process was calculated to possess a barrier and reaction exothermicity of 42.7 and 51.0 kJ mol^{-1} , respectively. Relative to the starting point in this pathway, the energy of this latter H-atom abstraction TS is 83.2 kJ mol^{-1} , which suggests a rate approximately two orders of magnitudes too slow relative to experiment. Zero-point vibrational energy, thermal effects, and solvation were found to have a large influence ($\sim 30 \text{ kJ mol}^{-1}$) on reducing the energy of this TS.

In a subsequent and more comprehensive study, the class III RNR-catalyzed reaction was re-examined using a larger model that included, in addition to the substrate, Cys290, Asn78, Cys79, Asn311, and two formates (Scheme 5).¹³¹ One neutral formic acid was used to mimic the function of Glu144 in the related class I RNR, which facilitates the loss of water from C2' of the ribose. The second (anionic) formate was placed near two asparagines, which were previously suggested to serve as a carboxylate binding site. Unlike the previous small-model study,¹³⁰ which examined just two steps (cf. steps f and g, Scheme 5), the entire reaction pathway was examined in the second investigation.¹³¹

The barrier and reaction enthalpy for the initial H-atom abstraction (step a, Scheme 5) from C3' of the ribose by the Cys290 radical were calculated to be 18.8 and 20.0 kJ mol^{-1} , respectively. The high energy of the product was found to be due to solvation effects. Formic acid plays a critical role in the subsequent loss of water and the generation of a resonance-stabilized radical of the form $\text{O}=\text{CR}-\text{C}^{\cdot}\text{RH}$ (step b). Indeed, the product state of this step was found to be lower in energy than the reactant state, so it was suggested that steps a and b might be concerted. In the following step, C2' is proposed to abstract an H atom from Cys79. Two energetically similar pathways were located for this transformation. The direct

H-atom-transfer pathway (step c) possesses a barrier of 35.6 kJ mol^{-1} . An alternative pathway (steps d and e) that involves the intermediacy of H_3O^+ was located and found to possess a barrier of 37.2 kJ mol^{-1} . Clearly, neither pathway can be ruled out on energy grounds. However, the authors note that there may be advantages in utilizing a small mobile H_3O^+ species rather than directly involving a cysteine residue.¹³¹

The next step in the reaction generates $\text{CO}_2^{\cdot-}$ via H-atom abstraction by Cys79 from the formate coordinated by the two asparagines (step f, Scheme 5). We note that the combination of this form of the substrate, Cys79, and formic acid represents the starting point for the preliminary small-model study of Cho *et al.*¹³⁰ In the larger model study, the barrier is calculated to be 13.8 kJ mol^{-1} and the step is slightly endothermic (by 10.3 kJ mol^{-1}).¹³¹ The O3' atom can then abstract an H atom from the nearby formic acid to localize the spin density on C3' (step g). This step is found to be rate limiting, possessing a barrier of 48.9 kJ mol^{-1} , which is well below the experimental upper limit of $\sim 70 \text{ kJ mol}^{-1}$. Formally, this step transfers the unpaired electron spin density from $\text{CO}_2^{\cdot-}$ to C3' via HCO_2 . The last step in the catalytic pathway (step h) is virtually just the reverse of the first step in that it involves the transfer of an H atom from Cys290 to C3'. With solvation included, it is found to be endothermic by 6.4 kJ mol^{-1} and to have no barrier.

The calculations performed with the larger model have thus identified an energetically feasible manner for the generation and action of the $\text{CO}_2^{\cdot-}$ reductant. The key difference with the smaller model study is the inclusion of one molecule of formic acid (as a Glu mimic) to catalyze the water loss and another (anionic) formate to serve as a proton and electron source, rather than relying on a single formic acid to perform both functions. While this mechanism is yet to be proven, it nevertheless demonstrates the usefulness of computations in mechanistic enzymology.

5 METHYL-COENZYME M REDUCTASE

In methanogenic archaea, methyl-coenzyme M reductase (MCR) catalyzes the exergonic conversion of methyl-coenzyme M ($\text{CoMS}-\text{CH}_3$) and

Figure 10 Crystal structure of the active site of the MCR_{ox1} -silent state (PDB code: 1MRO¹³³).

coenzyme B (CoB-SH) into methane and the heterodisulfide of coenzyme M (CoM-SH) and coenzyme B (14)¹³²:

MCR contains a redox-active nickel-centered tetrahydrocorphinoid coenzyme (F_{430}) in its active site, which lies at the bottom of a 30-Å-deep hydrophobic pocket. The active form of MCR, called MCR_{red1} , possesses a low-valent Ni(I) ion. Figure 10 shows the X-ray crystal structure of the MCR_{ox1} -silent form of MCR, in which the nickel is in the 2+ oxidation state, with one bound CoM substrate analog and one CoB.¹³³ Despite considerable efforts, details of the reaction mechanism are still unclear, with several different mechanisms proposed.

In mechanism I, nucleophilic attack of Ni(I) on the methyl group of $\text{CH}_3\text{-SCoM}$ results in heterolytic cleavage of the C-S bond to generate an organometallic $\text{CH}_3\text{-Ni(III)F}_{430}^+$ intermediate and the CoMS^- thiolate anion, which is then protonated by CoBSH to form CoBS^- and CoM-SH (step I.1, Scheme 6). The $\text{CH}_3\text{-Ni(III)F}_{430}^+$ intermediate is a strong oxidant and in the next step (I.2), it

is proposed that CoM-SH is oxidized to form a CoMS-H^+ thiyl radical cation plus a $\text{CH}_3\text{-Ni(II)}$ species. Protonolysis of the latter using the CoMS-H^+ thiyl radical cation then yields methane, the Ni(II) state of F_{430} , and the $\text{CoM-S}^\bullet$ thiyl radical. Finally, the $^\bullet\text{SCoM}$ thiyl radical and CoBS^- react to form a disulfide radical anion, which reduces Ni(II) back to its resting state Ni(I) (step I.3).

To determine the feasibility of mechanism I (Scheme 6), Pelmeshnikov *et al.*¹³⁴ examined the energy cost of methyl binding to nickel by comparing bond strengths relevant to the MCR-catalyzed reaction. It was concluded that an Ni-CH₃ bond is too weak to compensate for the energy required to break the $\text{CH}_3\text{-SCoM}$ bond. Indeed, the reaction step involving $\text{CH}_3\text{-S-CoM} + \text{Ni(I)F}_{430} \rightarrow ^\bullet\text{S-CoM} + \text{CH}_3\text{-Ni(II)F}_{430}$ (step I.1, Scheme 6) was calculated to be endothermic by $\sim 190 \text{ kJ mol}^{-1}$. More recently, the possibility of an Ni-CH₃ intermediate was examined by explicitly calculating TSs and intermediates for stepwise and concerted methyl additions to Ni(I) using $\text{CH}_3\text{-I}$, $\text{CH}_3\text{-Br}$, $\text{CH}_3\text{-Cl}$, and $\text{CH}_3\text{-S-CH}_3$ as substrates, where the latter structure was used as a model for $\text{CH}_3\text{-SCoM}$.¹³⁵ Stepwise methyl transfers from the methyl halides to Ni were calculated to possess quite low barriers ($\sim 16\text{--}28 \text{ kJ mol}^{-1}$), which is consistent with experimental observations of the reactions of MCR_{red1} with alkyl halides. Tyr333 and Tyr367 were found to stabilize the leaving halide anions and facilitate bond cleavage, while the barriers for binding the Gln147 oxygen to Ni were found to be small ($5\text{--}10 \text{ kJ mol}^{-1}$). The species were described as resonance structures between the “doublet-triplet” $\downarrow\text{CH}_3\text{-}\uparrow\uparrow\text{Ni(II)}$ radical state and the “anion-doublet” $\text{CH}_3^--\uparrow\text{Ni(III)F}_{430}$ state. Concerted TSs involving the simultaneous transfer of methyl from the substrate to Ni and the binding of Gln147 to Ni were found to possess larger barriers (of $\sim 40\text{--}55 \text{ kJ mol}^{-1}$) than those observed for the stepwise pathways. Interestingly, when $\text{CH}_3\text{-S-CH}_3$ is used as a substrate, only a concerted TS could be located, which led directly to the hexacoordinated $\text{CH}_3\text{-Ni(F}_{430})$ intermediate. While the reactions involving methyl halides were exothermic, the reaction of $\text{CH}_3\text{-S-CH}_3$ was calculated to be endothermic by $\sim 100 \text{ kJ mol}^{-1}$ and described as “unreachable.”¹³⁵

Because of these large energy requirements, Pelmeshnikov *et al.*¹³⁴ have instead proposed

Scheme 6 Possible mechanisms for methane formation by MCR.

another mechanism. Here, Ni(I) reacts with $\text{CH}_3\text{-SCoM}$ to promote homolytic cleavage of the C–S bond to give a methyl radical plus an Ni(II)-thiolate complex (mechanism II, step II.1). The methyl radical is then proposed to abstract an H atom from CoBSH to generate a CoBS $\cdot$ thiyl radical and release CH_4 (step II.2), which then reacts with the Ni(II)-thiolate complex to form a disulfide radical anion (step II.3). As in mechanism I, this radical anion then reduces Ni(II) back to its resting state Ni(I).

At the time the study was carried out, the large system size (107 atoms) precluded the calculation of an accurate TS, so comparisons with a smaller model were used for its estimation.¹³⁴ The barrier for direct methane formation involving CoBSH and $\text{CH}_3\text{-SCoM}$ was calculated to be 118.4 kJ mol^{-1} , which was revised to 81.6 kJ mol^{-1} when estimates for zero-point energy, entropy, and solvation were included. A feature of this mechanism is that it rationalizes the experimentally observed stereoinversion at the reactive carbon atom as well as rationalizing the inactivity of MCR in the presence of trifluoromethyl-coenzyme M ($\text{CF}_3\text{-S-CoM}$). Indeed, the $\text{CF}_3\cdot$ radical is predicted to possess a very large inversion barrier (of $\sim 100\text{ kJ mol}^{-1}$). However, this mechanism is not supported by the findings that MCR fails to catalyze the reduction of allyl-CoM, although this latter species acts as a competitive inhibitor.¹³⁶ Indeed, the formation of a free allyl radical would be expected to be significantly more favorable than the formation of a free methyl radical.

The mechanism of heterodisulfide product formation (mechanism II, step II.3) was examined in a subsequent paper.¹³⁷ In principle, upward deformation of the corphin ring of the CoM-S-Ni(II) intermediate to interact with the $\text{CoB-S}\cdot$ radical could occur. However, relaxed scans along the Ni-S_{CoM} and $\text{S}_{\text{CoM-S}_{\text{CoB}}}$ bonds indicate this to be a high-energy process ($>70\text{ kJ mol}^{-1}$). In contrast, a late TS describing heterodisulfide product formation was located and found to possess a barrier of 39.7 kJ mol^{-1} , indicating that methane formation (and not heterodisulfide product formation) is the rate-limiting step for this reaction.

In a third mechanistic proposal based on DFT (B3-LYP) calculations, Duin and McKee¹³⁸ favor a mechanism (mechanism III, Scheme 6) that begins with protonation of the F_{430} cofactor on the

C-ring nitrogen of the tetrapyrrole ring. Protonation at the Ni site was also examined and found to be $\sim 5\text{ kJ mol}^{-1}$ lower in energy. However, it is proposed that the side-chain amido group of Gln147 acts as a proton relay to the C-ring nitrogen of the Ni(I) F_{430} cofactor. Protonated Gln147 was found to lie 46.0 kJ mol^{-1} higher in energy than the structure with the proton on the C-ring nitrogen. The H-atom transfer barrier from Gln147 to the ring is calculated to be 92.0 kJ mol^{-1} . Activation of $\text{CH}_3\text{-SCoM}$ occurs with its oxidative addition to Ni to form a four-coordinate Ni product complex involving CH_3 , SCoM^{2-} , and two of the four nitrogen atoms from the corphin ring (step III.1, Scheme 6). A large barrier of 96.7 kJ mol^{-1} is predicted for this step and the reaction is endothermic by 42.3 kJ mol^{-1} . The Ni atom was found to move $1.5\text{ \AA}$ out of the approximate plane formed by the four corphin nitrogen atoms. This feature was highlighted as being an important ingredient in the mechanism because it allows the SCoM^{2-} ligand to approach more closely to the CoBSH cofactor than would otherwise be possible. In the next step (III.2), $\text{CoBS}\cdot$ was constrained above the F_{430} cofactor to mimic the enzyme environment. The complexation energy was calculated to be 44.4 kJ mol^{-1} relative to the separated $\text{CoBS}\cdot$ and $\text{F}_{430}\text{:SCoM}$ species. Most of the unpaired spin density was located on the sulfur atoms of each cofactor and the interaction was described as a two-center, three-electron ($2c\text{-}3e$) bond. The next step (III.3) results in the formation of the $\text{CH}_3\text{S-SCoM}\cdot$ radical anion ligand. This complex is calculated to lie 31.4 kJ mol^{-1} higher in energy than the $2c\text{-}3e$ intermediate. A barrier of 22.6 kJ mol^{-1} is determined for loss of CH_4 , via proton transfer to the CH_3 group from the C-ring nitrogen of the Ni(I) F_{430} . This final step (III.4, Scheme 6) regenerates Ni(I) F_{430} and is exothermic by the remarkable amount of 267.0 kJ mol^{-1} .

Some aspects of this proposed mechanism are difficult to reconcile with the available experimental evidence. For instance, inversion of stereochemistry is known to occur for the $\text{EtSCoM}\cdot$ cofactor and is generally believed to be operative for the native $\text{MeSCoM}\cdot$ cofactor as well. However, this mechanism does not account for this behavior. A pathway involving inversion of stereochemistry was found, but it was associated with a barrier of 138.9 kJ mol^{-1} , which is not likely to be competitive. Moreover, MCR

has recently been shown to catalyze the (reverse) conversion of CH₄ into methyl-coenzyme M under equilibrium conditions.¹³⁹ The very large exothermicity for CH₄ loss in the final step in this mechanism (267.0 kJ mol⁻¹) instead suggests an irreversible pathway. It was proposed that a reversible pathway could exist if the CH₄ loss occurs simultaneously with the reformation of protonated Ni(I)F₄₃₀.¹³⁸

Finally, for completeness, we note that a fourth mechanism has been proposed for the MCR-catalyzed reaction,¹⁴⁰ though it has not yet been examined computationally. On the basis of the transient kinetic measurements using EPR and UV-visible spectroscopy with the substrate analogs 2-bromoethanesulfonate and CoB₆SH, mechanism IV is a variation of mechanism I insofar that the first two steps are identical, but mechanism IV includes radical intermediates (Scheme 6). Following the generation of the CH₃-Ni(II) intermediate, proton transfer from the CoMSH⁺ radical cation generates CH₄ plus a CoMS[•] radical (step IV.3). An equilibrium of S-based radical intermediates is then proposed to occur (step IV.4). In step IV.5, condensation of CoMS and CoBS species leads to the formation of a disulfide radical anion, which then reduces Ni(II) back to its resting state Ni(I), as also proposed in mechanisms I and II.

6 CONCLUSIONS

The aim of this review has been to describe the insights that can be gained from computational investigations of radical enzymes. Of the many possible enzyme systems that may fall into the category, we have focused on a few selected examples to illustrate how these systems operate and how theory may be used to enhance our understanding. For the AdoCbl-dependent enzymes, theoretical investigations have provided mechanisms for how these enzymes activate the Co-C bond of AdoCbl, how partial protonation and deprotonation facilitate the otherwise difficult rearrangement step, and how the inherent stability of the participating radical intermediates can profoundly affect the level of catalysis. Likewise, computational investigations have characterized intermediates and demonstrated the importance of certain active-site amino acid residues in the reactions catalyzed by PFL, BSS, and class III RNR. In the case of MCR, the use

of theory has offered new mechanistic ideas as to how this enzyme operates, which can then be tested experimentally. Overall, it is clear that the combination of experimental and computational investigations provides an excellent and highly synergistic approach to elucidate the cause-and-effect actions that govern enzyme catalysis.

Lipid Peroxidation

Etsuo Niki

*Health Research Institute, National Institute of Advanced Industrial Science and Technology,
Ikeda, Osaka, Japan*

1 INTRODUCTION

Free and ester forms of fatty acids and cholesterol are physiologically important lipids that are essential components of cellular membranes. Lipids containing polyunsaturated fatty acids (PUFAs) are quite susceptible to oxidant attack and their free-radical-mediated oxidation by molecular oxygen, referred to as *lipid peroxidation* (LPO), results in deleterious effects.^{1,2} The term *peroxidation* refers to dioxygenation and some oxidation of lipids proceeds, as described later, by monooxygenation, but the term “LPO” is used in this article to show the oxidation of lipids in general. LPO was first studied in 1930s in relation to the deterioration of foodstuffs. The autooxidation, oxidation by molecular oxygen, of lipids is responsible for rancidity in fat-containing food products. With increasing evidence showing the involvement of free radicals in health and disease, free-radical-mediated LPO has received renewed attention from wider viewpoints in the fields of chemistry, biochemistry, biology, nutrition, pharmacology, and medicine.^{3,4} LPO is now implicated in the pathogenesis of various diseases such as atherosclerosis, neurodegenerative diseases, cancer, inflammation, and cataract. For example, it was known in 1950s that LPO products were present in the atherosclerotic plaques⁵ and it is now generally accepted that LPO results in the modification of low density lipoprotein (LDL) and high density lipoprotein (HDL), which is a key initial event for the progression of atherosclerosis.⁶ Later studies

revealed that, similar to proteins, carbohydrates, and nucleic acids, lipids are targets of various reactive oxygen species (ROS) and reactive nitrogen species (RNS) and oxidized to give a diverse array products (see **Biological Chemistry of Reactive Oxygen Species**). The mechanisms, dynamics, and products of LPO *in vitro* have been studied extensively and are now fairly well understood and documented,^{1,7,8} but the physiological levels and biological effects of LPO and its products have not been well elucidated yet.

It has been shown that LPO induces disturbance of fine structure and alteration of integrity, fluidity, and permeability, and functional loss of biomembranes. Free radical addition–fragmentation as well as LPO induces the cis–trans isomerization, which may result in loss of important structural information linked to biological activity⁹ (see **Lipid Isomerization**). LPO also modifies LDL to pro-atherogenic and pro-inflammatory forms, and generates potentially toxic products. LPO products have been shown to be mutagenic and carcinogenic.¹⁰ As described later, the reactive carbonyl compounds, the secondary products of LPO, modify biologically essential molecules such as proteins and DNA bases.¹¹ Thus LPO *in vivo* has been implicated as the underlying mechanisms in numerous disorders and diseases such as cardiovascular diseases, cancer, neurological disorders, and aging. Consistent with this notion, numerous studies show increased levels of LPO products in the biological fluids and tissues from the patients,

Scheme 1 Structures of representative lipid peroxidation products H(P)ODE and H(P)ETE.

although the question whether LPO is a cause or consequence of these events is still not clear and remains to be elucidated in the future studies. In any event, the levels of LPO products such as hydro(pero)xyoctadecadienoic acid, H(P)ODE, and hydro(pero)xyeicosatetraenoic acid, H(P)ETE, produced in the oxidation of linoleic acid and arachidonic acid, respectively may serve as reliable marker for oxidative stress *in vivo*. The representative structures of H(P)ODE (**1** and **2**) and H(P)ETE (**3** and **4**) are shown in Scheme 1. Several regio- and stereoisomers are formed as described later.

At the same time, it became evident recently that LPO products as well as ROS/RNS exert various biological functions *in vivo* such as regulator of gene expression, signaling messenger, activator of receptors and nuclear transcription factors, and inducer of adaptive response^{12,13} (see **Free Radicals and Metabolic Disorders**). Recent studies provided evidence that many LPO products exert opposite dual effects depending on the conditions such as cytotoxic and cytoprotective effects, pro- and anti-atherogenic effects, pro- and anti-apoptotic effects, and pro- and anti-inflammatory effects.^{14,15} However, the physiological significance of such

effects by LPO products observed in cultured cell systems is not clear yet.

2 THREE MECHANISMS OF LPO

It has been known that LPO proceeds by three distinct mechanisms, that is, (i) free-radical-mediated chain oxidation, (ii) free radical-independent, nonenzymatic, stoichiometric oxidation, and (iii) enzymatic oxidation.¹ Characteristic products are formed from the respective mechanisms and specific antioxidants are required to inhibit each type of LPO. Singlet oxygen, ozone, and hypochlorite are typical oxidants which oxidize lipids by nonradical mechanism, whereas lipoxygenase (LOX), cyclooxygenase (COX), and cytochrome P450 (CYP) are important enzymes which oxidize lipids *in vivo*. The characteristics of each type of oxidation are summarized in Table 1, together with the major products from arachidonic acid (20:4) as an example of substrate lipid.

The characteristics of nonradical oxidation and enzymatic oxidation are described briefly below and the mechanism and products of free-radical-mediated LPO are described in detail in the subsequent section.

Table 1 Hydro(pero)xyeicosatetraenoic acid (H(P)ETE) isomers produced in the oxidation of arachidonic acid by different oxidants.^a

Oxidant	Isomers		
	Regio	Stereo	Enantio
Free radical	5, 8, 9, 11, 12, 15	cis,trans, trans,trans	<i>R</i> = <i>S</i>
Lipoxygenase	5, 12, 15	cis,trans	<i>R</i> or <i>S</i>
Cytochrome <i>P</i> 450	5, 8, 9, 11, 12, 15, 19, 20	cis,trans	<i>R</i> or <i>S</i>
Singlet oxygen	5, 6, 8, 9, 11, 12, 14, 15	cis,trans	

^a Oxidation by free radical, lipoxygenase, and singlet oxygen gives HPETE, while that by cytochrome *P*450 gives HETE as primary product.

2.1 Nonradical, Nonenzymatic Oxidation of Lipids

Singlet oxygen and ozone oxidize lipids by nonradical mechanisms. Singlet oxygen oxidizes unsaturated lipids mainly by ene-reaction to give hydroperoxide with concomitant double bond migration, with minor side reactions such as 1,4-addition to give 1,4-endoperoxide and 1,2-addition to give dioxetane, which readily decomposes to yield carbonyl compounds accompanying chemiluminescence.¹⁶ For example, the oxidation of linoleates by singlet oxygen gives 9-, 10-, 12-, and 13-hydroperoxyoctadecadienoic acid (HPODE 1), 10- and 12-HPODE being specific products for singlet oxygen oxidation.¹⁷ Squalene hydroperoxides formed by singlet oxygen have been observed in sunlight-exposed human skin.¹⁸

Ozone oxidizes double bonds to give ozonide as a primary product, which is unstable and readily undergoes secondary reactions to give cleavage products.¹⁹ It was reported that the cholesterol oxidation products by ozone were found in atherosclerotic plaque.²⁰ Recently it was found, however, that the products were formed in the oxidation of cholesterol by either ozone or singlet oxygen.^{21–23}

Hypohalide is an oxidant generated by the action of myeloperoxidase (MPO) with hydrogen peroxide and halide ion. MPO, a heme protein secreted by activated phagocytes, reacts with hydrogen peroxide in the presence of chloride and bromide to give hypochlorous acid and hypobromous acid, HOCl and HOBr, respectively, which are strong oxidants and oxidize biological molecules by several mechanisms including both free radical and nonradical pathways.^{24,25} It was reported that MPO and tyrosine produced tyrosyl radical and induced LPO.²⁶ The dissociated forms of hypochlorite and hypobromide oxidize lipids to give

chlorohydrines and bromohydrines, respectively, which yield epoxides. Hypochlorite reacts with hydrogen peroxide to yield singlet oxygen, while it reacts with organic hydroperoxides to give alkoxyl and/or peroxy radicals, with little concomitant formation of singlet oxygen.^{27,28} In support of this, it was observed that the oxidation of methyl linoleate by hypochlorite gave racemic 9- and 13-, *cis,trans*- and *trans,trans*-conjugated diene hydroperoxides, clearly showing that the oxidation proceeded by free radical mechanism. The rate constants for the reaction of hypochlorite with hydrogen peroxide and *tert*-butyl hydroperoxide were estimated as 1700 and 43 M^{−1} s^{−1}, respectively at 37 °C,²⁷ which are much smaller than those of hypochlorite with amino acids.²⁵ Hypochlorite and hypobromide react with amines much faster than with lipids to give chloramines and bromoamines, respectively, which undergo homolytic cleavage to give free radicals together with aldehydes.²⁹ These radicals may induce LPO.

2.2 Enzymatic Oxidation of Lipids

The enzyme-mediated oxidation of lipids has been the subject of extensive studies, because the products, above all those derived from arachidonic acid which are referred to as “eicosanoids,” have been found to exert potent biological functions and activities. Currently, over a hundred different eicosanoids have been identified and they have been implicated in a number of inflammatory and life-related diseases such as atherosclerosis, arthritis, and cancer.³⁰ It has been known that LOX and COX oxidize arachidonic acid to HPETE 3, prostaglandins, prostacyclin, thromboxane, and leukotrienes.

In contrast to free radicals, COX and LOX oxidize lipids regio-, stereo-, and enantiospecifically.³¹ For example, 15-LOX oxidizes linoleates to

give 13(*S*)-9-*cis*,11-*trans*-HPODE **1** exclusively, while the free-radical-mediated oxidation of linoleates gives four racemic products. Soybean LOX catalyzes the conversion of linoleic acid into 13(*S*)-9-*cis*,11-*trans*-HPODE **1**, but tomato or corn seed LOX preferentially produces 9(*S*)-10-*trans*,12-*cis*-HPODE **5**.³² LOX directly oxidizes fatty acid residues of phospholipids and cholesteryl esters in LDL particles as well as free fatty acids, although the stereo- and enantiospecificity decreases.^{33,34} It is also known that CYP oxidizes arachidonic acid to give hydroxyecosatetraenoic acid (HETE) **4**, epoxyecosatrienoic acid (EET), and dihydroxyecosatetraenoic acid.³⁵

It may be noted that the specificity of LOX oxidation depends on the reaction milieu. As mentioned above, 15-LOX oxidizes linoleates regio-, stereo-, and enantiospecifically, while free-radical-mediated oxidation gives random, racemic products. It was observed that the enantiospecificity in the oxidation of linoleates in LDL particles by 15-LOX was *S/R* = 71:29, while the products in the oxidation induced by copper were stereo-random and racemic, *S/R* being 50:50 as expected.³³ It was also found that the oxidation of phosphatidylcholine (PC) and cholesteryl esters in the plasma and membranes gave specific products preferentially, but with decreased specificity compared with the oxidation of free acids in aqueous solution.^{34,36}

3 FREE-RADICAL-MEDIATED LPO

3.1 Mechanisms of LPO

The free-radical-mediated LPO proceeds by a chain mechanism, that is, one initiating free radical can

oxidize many lipid molecules. It was confirmed experimentally that chain reactions proceed in the oxidation of biological membranes³⁷ and LDL³⁸ *in vitro* with considerably long kinetic chain length, but it is difficult to measure the kinetic chain length of LPO *in vivo*. The mechanism of chain initiation and the responsible initiating free radicals *in vivo* have been argued extensively, but the details are not fully elucidated yet. Different types of active species may be involved under different conditions. The relevant free radicals and their kinetic parameters are summarized in Table 2. Hydroxyl radical may be formed by the reaction of hydrogen peroxide and ferrous ion (Fe^{2+}) (Fenton reaction) or cuprous ion (Cu^+), from peroxyxynitrite, or high energy irradiation. Alkoxyl radical may be formed in the decomposition of hydroperoxides by metal ions such as heme proteins and copper (Haber–Weiss reaction). Metals may contribute in the chain initiation step directly as well. Superoxide and nitric oxide (NO) are produced from enzymes such as NADPH oxidase, xanthine oxidase, and nitric oxide synthase. Neither superoxide nor NO is active enough *per se* to initiate LPO directly, but they react quite rapidly at diffusion controlled rate to give peroxyxynitrite, which may initiate LPO chain reaction.^{39,40} Superoxide is not reactive as a radical, but it may contribute to free radical generation by reducing transition metal ions to more reactive lower valency state, for example, Fe(III) to Fe(II). Nitrogen dioxide may be formed from NO or inhaled from cigarette smoke or polluted air. It is not a reactive free radical, but may add to the double bond of unsaturated lipids and initiate chain reaction. As shown above, free radicals may also be formed by MPO. It may be noted that even α -tocopheroxyl radical, a radical produced from vitamin E, a major antioxidant *in vivo*, can

abstract hydrogen atom from PUFAs at appreciable rate constant (Table 2).⁴¹ It should be emphasized that the chain propagation is carried by lipid peroxy radicals independent of the type of chain-initiating free radicals.

The mechanism of free-radical-mediated LPO has been studied extensively, most notably by Porter and his colleagues.^{7,8} The major reactions include (i) abstraction of bisallylic hydrogen from PUFAs to give carbon-centered radical, which is highly delocalized and rearranges to more stable *cis*,*trans*-pentadienyl radical, (ii) addition of oxygen to the pentadienyl radical to give lipid peroxy radical, (iii) release of oxygen from the peroxy radical to give oxygen and pentadienyl radical, (iv) rapid reaction of the pentadienyl radical with oxygen to give thermodynamically more stable *trans*,*trans*-form preferentially than *cis*,*trans*-form, and (v) intramolecular addition of the peroxy radical to the double bond to yield bicyclic prostaglandin-type products (Scheme 2). The important chain propagation step is the abstraction of bisallylic hydrogen from polyunsaturated lipids by lipid peroxy radical to give conjugated diene lipid hydroperoxide and new lipid radical, which continues another chain propagation sequence. The product distribution is determined by the relative importance of these many competing reactions of different types of free radicals.

The LPO of linoleic acid and its esters has been studied extensively, since they are the most abundant polyunsaturated lipids *in vivo* and their oxidation proceeds by a straightforward mechanism to give much simpler products with high selectivity than arachidonates and other more highly unsaturated fatty acids. The free-radical-mediated oxidation of linoleates proceeds by the steps 1–4 mentioned above to give four conjugated diene hydroperoxides **1**, **5**, **6**, and **7** quantitatively (Scheme 3). LPO of linoleates is initiated by the abstraction of hydrogen at C11 to yield a pentadienyl radical. Unlike specific hydrogen abstraction by LOX, both C11 bisallylic hydrogens are abstracted equally. Nonconjugated C11-hydroperoxide **8** is obtained from linoleates only in the presence of high concentration of potent hydrogen donor such as α -tocopherol.⁴² Oxygen adds to the pentadienyl radical at either C9 or C13 to give the corresponding *cis*,*trans*-peroxy radical. The kinetic products, 9-10-*trans*,12-*cis*-HPODE **5** and 13-9-*cis*,11-*trans*-HPODE **1**, are formed by hydrogen abstraction, but under such conditions that potent hydrogen donor is not present, the *trans*,*cis*-peroxy radical at C9 or C13 can undergo β -fragmentation to yield original *cis*oid-pentadienyl radical or *trans*oid-pentadienyl radical if bond rotation precedes β -fragmentation. The process of β -fragmentation was studied in detail using

Scheme 2 Pathways of free-radical-mediated lipid peroxidation.

Scheme 3 Mechanisms of peroxidation of linoleic acid. R^1 : $-(\text{CH}_2)_7\text{COOH}$, R^2 : $-(\text{CH}_2)_4\text{CH}_3$.

^{18}O labeled methyl linoleate hydroperoxide.⁴³ The rate constant for β -fragmentation of dienyloperoxyl radicals leading to transoid centers was found to be 16 times larger than that leading to cisoid centers, 430 and 27 s^{-1} , respectively.⁴⁴ The thermodynamic products, 9-*trans,trans*- and 13-*trans,trans*-HPODE, **6** and **7** respectively, can be obtained by oxygen addition to *trans,trans*-radical followed by hydrogen abstraction. It was found that in the oxidation of methyl linoleate under air in acetonitrile solution induced by a constant flux of free radicals generated from azo initiator, the amounts of methyl linoleate consumed, oxygen uptaken, conjugated diene formed, and hydroperoxide formed agreed well,⁴⁵ suggesting that methyl linoleate was oxidized by a straightforward mechanism to give methyl esters of four conjugated diene HPODE quantitatively. It is noted that the amounts of HPODE **1** and **5** are equal and **6** and **7** are equal and that they are racemic, that is, equal amounts of *R* and *S* forms are formed.

Compared with linoleic acid, the oxidation of more highly unsaturated fatty acids having more than three double bonds such as linolenic acid

(18:3), arachidonic acid (20:4), eicosapentaenoic acid (EPA) (20:5), and docosahexaenoic acid (DHA) (22:6) proceeds by more complicated mechanisms including intramolecular addition reaction to give numerous products such as prostaglandin-type cyclic peroxides as well as hydroperoxides. Serial cyclic peroxides as well as monocyclic peroxides have been identified in the oxidation of arachidonates.⁸ Nonetheless, the oxidation proceeds by a combination of the elementary reactions mentioned above. The importance of intramolecular addition reaction relative to hydrogen abstraction is determined by the concentrations of reactive hydrogen and oxygen (Scheme 2).

Arachidonates have three centers at C7, C10, and C13 that have carbons flanked by two double bonds. The six bisallylic hydrogens on these carbons are attacked similarly by peroxy radicals to form three pentadienyl radicals. Oxygen adds to either end of the radicals giving 5-, 8-, 9-, 11-, 12-, and 15-eicosatetraenylperoxyl radicals, having *trans*-*cis* diene geometry. Hydrogen atom abstraction by these peroxy radicals gives the corresponding six regioisomers of *trans,cis*-HPETEs. The 8-, 9-, 11-, and

Table 3 Distribution of HPETE regioisomers formed in the oxidation of 1-palmitoyl-2-arachidonoyl-*sn*-glycero-3-phosphocholine, PC(16:0/20:4).

HETE	In methanol		In liposomes	
	Antioxidant: none		α -Tocopherol	Trolox
5-HETE	31.3	39.6	23.1	37.1
8-HETE	7.3	4.3	11.1	5.1
9-HETE	8.6	7.8	16.6	7.1
11-HETE	8.9	5.9	12.0	6.2
12-HETE	10.4	9.6	14.8	8.2
15-HETE	33.0	32.6	22.5	36.3

Source: Reproduced from the data in Ref. 46.

^aThe oxidation of PC(16:0/20:4) liposome was performed at 30 °C in tris-HCl buffer (pH 7.4) for 3 h and HETEs were analyzed after treatment with triphenylphosphine. Values are mean percentage of several experiments ($n > 5$). For simplicity, standard deviation is not shown.

12-peroxyl radicals have isolated double bonds placed such that a 5-exo-cyclization can occur and the intramolecular cyclization of these four peroxyl radicals proceeds faster than β -fragmentation and therefore few *trans,trans*-HPETE is formed from these peroxyl radicals. On the other hand, 5- and 15-peroxyl radicals cannot undergo intramolecular cyclization and may give the corresponding *trans,trans*-HPETEs.

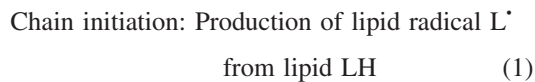

The distribution of HPETEs obtained in the oxidation of 1-palmitoyl-2-arachidonoyl PC liposomes in aqueous dispersions induced by free radicals is shown in Table 3.⁴⁶ The products were treated with triphenylphosphine to convert HPETEs to the corresponding HETEs. The results in Table 3 support the above statements that 5- and 15-HETEs yields are higher than those of 8-, 9-, 11-, and 12-HETEs, which are formed similarly. The addition of hydrogen-donating antioxidant α -tocopherol, but not Trolox, increased relative amounts of 8-, 9-, 11-, and 12-HETEs by scavenging peroxyl radicals before they undergo intramolecular addition reaction. Hydrophilic antioxidant Trolox localized in the aqueous phase cannot scavenge peroxyl radicals within the lipophilic compartment efficiently and its effect on regioisomer distribution of HETEs was small (see **Antioxidants in Chemistry and Biology**).

3.2 Dynamics of LPO

Fatty acids are present *in vivo* mainly in ester forms such as phospholipids, glycerides, and cholesteryl esters as well as in free form. They are present in cellular membranes and lipoproteins.

The biological membranes and lipoproteins have characteristic structure and properties, but the free-radical-mediated LPO in the membranes and lipoproteins are assumed to proceed by substantially the same mechanisms and to give the same products as in homogeneous solution. The fatty acid distribution in membranes and lipoproteins depends on the type of tissues and also diets. Furthermore, cholesteryl esters and triacylglycerols contain relatively more linoleate and oleate, respectively. It has been observed that the LPO proceeds similarly in isolated LDL,⁴⁷ plasma,⁴⁸ erythrocytes,⁴⁹ whole blood,⁵⁰ tissues,⁵¹ and whole body.⁵² It may be noted, however, that the rate of and relative susceptibility to oxidation of lipids may change depending on the environmental characteristics such as heterogeneous distribution, fluidity, rigidity, and packing in the membranes and lipoproteins. For example, fatty acid moieties of cholesteryl esters present in the core of LDL particles are more readily oxidized than those in phospholipids localized in the outer surface of LDL particles, because LDL core is less rigid than the outer membrane.⁴⁷ It is known that the oxidizability of unsaturated fatty acids increases with increasing number of double bonds. However, it is also known that EPA and DHA reduce the oxidizability of micelles.⁵³

The chain reaction of LPO is expressed by a very simplified scheme shown below in sequence of equations from (1) to (5):

Chain termination: $2 \text{LO}_2^\bullet \longrightarrow \text{non-radical}$

products (4)

In the chain initiation step, a lipid radical is formed from the lipid (1). The lipid radical reacts with oxygen to give lipid peroxy radical (2). This reaction is a radical–radical coupling process, which proceeds rapidly at or near diffusion controlled rate with a rate constant of approximately $10^9 \text{ M}^{-1} \text{ s}^{-1}$. The resultant peroxy radical abstracts bisallylic hydrogen from PUFA (3) to yield lipid hydroperoxide and a new lipid radical, the rate constant being approximately $30 \text{ M}^{-1} \text{ s}^{-1}$ per active hydrogen. In the chain termination step, two lipid peroxy radicals react (4) or lipid peroxy radical is scavenged by an antioxidant (5) to give stable products.

In the absence of an antioxidant, the rate of LPO is given by (6):

$$\frac{-d[\text{O}_2]}{dt} = \frac{k_p[\text{LH}]R_i^{1/2}}{(2k_t)^{1/2}} \quad (6)$$

where k_p and k_t are the rate constants for chain propagation reaction (3) and chain termination reaction (4), respectively and R_i is the rate of chain initiation. LPO of phospholipids in lipid bilayers follows the same kinetic rate law as in homogeneous solution.⁵⁴

As described above, the hydrogen abstraction from PUFA by *trans,cis*-peroxy radicals from linoleates leading to *trans,cis*-HPODE and β -fragmentation of the peroxy radicals leading to *trans,trans*-HPODE compete and this competition has been used to “clock” the bimolecular atom transfer reaction,⁵⁵ that is, the rate constant for chain propagation step, k_p , is estimated from the ratio of *trans,cis*-H(P)ODE/*trans,trans*-H(P)ODE and the absolute rate constant k_p for linoleic acid measured by rotating sector method.⁵⁶ The rate constants k_p for PUFA and cholesterol obtained by this method are summarized in Table 4.⁵⁷ The estimated rate constants for hydrogen atom abstraction by peroxy and alkoxy radicals are also included in Table 4. It can be seen that the rate constants, that is, the reactivity toward

Table 4 Absolute rate constants ($\text{M}^{-1} \text{ s}^{-1}$) for hydrogen atom abstraction from PUFA and cholesterol by peroxy and alkoxy radicals.

Oxygen radical Lipid	Peroxy ^a	Peroxy ^b	Alkoxy ^b
Stearic (18:0)	—	10^{-3} – 10^{-4}	2.3×10^6
Oleic (18:1)	—	0.1–1	3.3×10^6

^cReference 56.

lipid peroxy radicals, increase with an increase in parallel with the number of double bonds and that cholesterol having no bisallylic hydrogen has much lower reactivity than PUFA. Application of this clock method to the oxidation of PC liposomal membranes gave relative chain propagation rate constants of arachidonate, eicosapentaenoate, and docosahexaenoate to be 115, 145, and 172, respectively, that parallels one in solution. Interestingly, it has been observed that linoleate peroxy radicals at different positions on the 18-carbon chain have different kinetic properties and C9-peroxy radical gives more *trans,cis*-HPODE or less *trans,trans*-HPODE than does the C13-peroxy radical.⁵⁷

3.3 Products of LPO

3.3.1 Lipid Hydroperoxides and Hydroxides

Lipid hydroperoxides are formed in LPO as the primary product. Above all, the oxidation of linoleates gives HPODE **1**, **5**, **6**, and **7** quantitatively, whereas the oxidation of fatty acids and esters having more than three double bonds gives cyclic peroxides in addition to hydroperoxides since intramolecular addition reaction of peroxy radical competes with the hydrogen atom abstraction. In the presence of potent hydrogen donor such as vitamin E, the yield of hydroperoxide becomes relatively higher. Lipid hydroperoxides are reduced *in vivo* by glutathione peroxidases (GPx) and selenoprotein P

to yield the corresponding hydroxides. Also lipid hydroperoxides may undergo secondary reactions to form various secondary products. As described above, LOX also oxidizes PUFA to give hydroperoxides and CYP gives hydroxides.

3.3.2 Aldehydes

Various small molecular weight aldehydes such as acrolein, malondialdehyde (MDA), and 4-hydroxy-2-nonenal (HNE) are formed during LPO as secondary or decomposition products.⁵⁹ More than 20 saturated and unsaturated aldehydes were identified and found in biological samples by a method based on the use of *O*-(2,3,4,5,6-pentafluorobenzyl) hydroxylamine hydrochloride to form the oxime, followed by trimethylsilylation of the hydroxyl group to trimethylsilyl ethers.^{60,61} Among them, HNE produced in the oxidation of *n*-6 PUFA has been studied most extensively,⁶² while 4-hydroxy-2-hexenal is an oxidation product of *n*-3 PUFA and may be important in tissues such as brain and retina.⁶³ The formation of aldehydes by MPO–hydrogen peroxide–chloride ion system may also be an important pathway *in vivo*.⁶⁴ It should be added that aldehydes are not only toxic end products and remnants of LPO but may also act as signaling mediator.

3.3.3 Epoxides

Epoxides are formed by both free-radical-mediated LPO and by CYP enzyme oxidation. Peroxyl radicals add to the double bond to yield an adduct, which undergoes β -scission to produce epoxide and alkoxyl radical (7).

As expected, the yield of epoxide increases with decreasing oxygen concentration.

The generation of EETs from arachidonic acid by *P*450 enzymes has been known well.⁶⁵ Arachidonic acid has four double bonds and 5,6-, 8,9-, 11,12-, and 14,15-EET are formed. Recently, the epoxidation of EPA and DHA has also received attention.⁶⁶

3.3.4 Ketones

Oxo-derivatives are also one of the major oxidation products of PUFA. They may be produced in the decomposition of hydroperoxides or directly in the biomolecular interactions of lipid peroxyl radicals (4). For example, 9- and 13-oxooctadecadienoic acids are formed in the oxidation of linoleic acid. Both *cis,trans*- and *trans,trans*-forms are formed.⁶⁷

3.3.5 Isoprostane (IsoP)

Since the discovery in 1990 by a group of Morrow and Roberts that isoprostanes (IsoPs) are formed by a free-radical-mediated oxidation of arachidonic acid independent of COX,⁶⁸ numerous studies have been performed on these interesting LPO products. IsoPs are a series of prostaglandin-like compounds (Scheme 4), of which F₂-IsoPs containing F-type prostane ring have been studied most extensively.⁶⁹ The 8-, 9-, 11-, and 12-peroxyl radicals, but not 5- and 15-peroxyl radicals, derived from arachidonic acid undergo two consecutive intramolecular cyclizations, oxygen addition (Scheme 2), and hydrogen abstraction to form PGG₂-like compounds, which are reduced by ketoreductase to give F₂-IsoPs. Compounds are denoted as 5-, 8-, 12-, and 15-series regioisomers depending on the carbon atom to which the side-chain hydroxyl is attached.⁷⁰ A total of 64 isomers of F₂-IsoPs can be formed from arachidonic acid. An important structural distinction between IsoP and COX-derived PGs is that the former contain side chains that are predominantly oriented *cis* to the prostane ring, whereas the latter possess exclusively *trans* side chain.⁶⁸ The prostaglandin H₂-like bicyclic endoperoxide intermediates isomerizes to yield D₂- and E₂-IsoP, which are unstable and spontaneously dehydrate to yield J₂- and A₂-IsoPs,⁷¹ chemically reactive electrophilic cyclopentenones. The oxidation of EPA and DHA by similar mechanisms gives F₃-IsoPs and F₄-neuroprostanes, respectively.⁷²

The product distribution is determined by the relative importance of many competing reactions. The 8-, 9-, 11-, and 12-peroxyl radicals derived from arachidonates may abstract hydrogen to give HPETE or undergo intramolecular cyclization to give cyclic peroxide containing carbon-centered

Scheme 4 Isoprostanes and isofurans.

radical, which may react with oxygen to give peroxyl radical or undergo exocyclization to form the bicyclic endoperoxide, which leads to the formation of IsoP. Therefore, with increasing concentrations of hydrogen donor and oxygen, the formation of IsoPs becomes disfavored. In agreement with this, it was found that isofurans having a substituted tetrahydrofuran ring structure becomes more favored with increasing oxygen concentration.⁷³

3.3.6 Nitro-Fatty Acids

Nitro-fatty acids are another class of interesting product.⁷⁴ Two allylic nitro derivatives of linoleic acid were found in human erythrocytes and plasma as both free and ester forms.⁷⁵ They were identified as 10-nitro-9-*cis*,12-*cis*-octadecadienoic acid and 12-nitro-9-*cis*,12-*cis*-octadecadienoic acid. Nitrated derivatives of all principal unsaturated fatty acids were detected in human plasma and urine.⁷⁶ More nitrated oleic acids were observed than nitrated linoleic acids.⁷⁶ A nitrated derivative of cholesteryl

linoleate was detected also in human plasma and lipoproteins.⁷⁷ Nitro-fatty acids are assumed to be formed by the initial addition of nitrogen dioxide radical and/or nitronium ion, NO₂⁺, to the double bond. Peroxynitrite and peroxynitrous acid may be involved as well.

3.4 Oxidation of Cholesterol

Cholesterol is another important constituent of biological membranes and exerts biological functions. Cholesterol physically stabilizes membrane and increases membrane rigidity, which makes the membrane more resistant to free radical attack from an external aqueous phase. Cholesterol is also an important substrate of oxidation and oxidized similarly as PUFA by three mechanisms mentioned above (Scheme 5).^{78–81} The oxidation products of cholesterol are named *oxysterols*. The free-radical-mediated oxidation of cholesterol gives 7-hydroperoxycholesterol (**12**, 7-OOHCh) as the primary product together with 7-hydroxycholesterol

Scheme 5 Major pathways and products of cholesterol oxidation.

(**13**, 7-OHCh), 7-ketocholesterol (**14**, 7-KCh), cholesterol-5,6-epoxide (5,6-epoxyCh), and cholestane-3 β ,5 α ,6 β -triol as major products. Both α and β forms of **12**, **13**, and 5,6-epoxyCh are formed. Although cholesterol does not have bisallylic hydrogen, it is oxidized significantly within cells to give hydroperoxide.⁸²

Singlet oxygen oxidizes cholesterol to give 5-HOOCh **10** as a major primary product. The oxidation of cholesterol by ozone has received attention, since it was reported that ozonolysis products of cholesterol were found in atherosclerotic plaques,²⁰ although there is some controversy about this finding.^{16,19} The ozonolysis products such as 5,6-secoesterol (3 β -hydroxy-5-oxo-5,6-secocholestan-6-al) (atheronal-A), its aldolization product (atheronal-B), and 5,6-epoxyCh have been found as major products from cholesterol.⁸³ It was reported recently that 5,6-secoesterol was formed by

Hock cleavage of 5 α -hydroperoxycholesterol **10**²¹ or from the MPO—hydrogen peroxide—chloride system,²³ not by ozonolysis. It was also reported that the reaction of cholesterol with singlet oxygen formed by photodynamic action of thermal decomposition of 1,4-dimethylnaphthalene endoperoxide gives atheronal-B.²² The oxidation of cholesterol by hypochlorite gives chlorohydrins and 5,6-dichlorocholesterol as major products.⁸⁴

Various enzymes oxidize cholesterol to give specific hydroxycholesterols.^{85,86} Many of the enzymes belong to the CYP family and are present in hepatocytes, but 24-hydroxylase, CYP46A1, is found exclusively in neuronal cells in brain and retina and gives 24(*S*)-OHCh as a specific product.⁸⁷ 7 α -Hydroxycholesterol **9**, an important intermediate in bile acid biosynthesis, is formed by cholesterol 7 α -hydroxylase (CYP7A1) as well as free radical oxidation. The drug-metabolizing

enzyme CYP3A4 oxidizes cholesterol to give 4 β -hydroxycholesterol. The mitochondrial enzyme CYP27A1 gives 27-hydroxycholesterol. 25-Hydroxycholesterol is formed by cholesterol 25-hydroxylase which is not a CYP enzyme.⁸⁸

It is assumed that 7 β -OHCh and 7-KCh are characteristic products formed by free-radical-mediated oxidation, but it should be noted that the interconversion between oxysterols has been found.⁸⁹ for example, the interconversion of 7 β -OHCh and 7-KCh by 11 β -hydroxysteroid dehydrogenase type 1 was confirmed to take place in humans.⁹⁰

3.5 Reactions of LPO Products

Many LPO products are not stable end products but they undergo various secondary reactions and react with proteins and DNA bases. Lipid hydroperoxides, the primary product of LPO, may be decomposed by transition metal ions and modify proteins by reacting with lysine residue.⁹¹ Cholesteryl hydroperoxide has been reported to induce DNA strand break and base modification.⁹² The α,β -unsaturated aldehydes such as HNE are highly reactive and readily react with proteins, DNA, and phospholipids to cause deleterious effects. Modification of amino acids of proteins and peptides by these aldehydes occurs mainly at cysteine, lysine and, to a lesser extent, histidine to form stable covalent-bonded adducts by Michael addition reaction across its carbon-carbon double bond.⁹³ Carbonyl groups of aldehydes may alternatively react with the amino groups to form Schiff bases. HNE can undergo both a Michael addition and a Schiff base formation with phospholipids such as phosphatidylethanolamine and phosphatidylserine. HNE- and acrolein-protein adducts are considered to be a good biomarker of LPO and protein modification *in vivo* and they have been applied widely by using antibodies directed against these adducts.^{93,94}

4 LIPID PEROXIDATION IN BIOLOGICAL SAMPLES

4.1 LPO of Low Density Lipoprotein

With increasing evidence showing the involvement of LPO in the pathogenesis of various diseases,

the LPO in biological samples have received much attention. Especially, the oxidation hypothesis presented by Steinberg and his colleagues⁶ that oxidative modification of LDL is the key initial event of atherosclerosis triggered extensive studies on the oxidation of LDL.

Human LDL is a spherical particle with a diameter of about 22 nm and an average molecular weight of 2.5 million. Neutral lipids such as cholesteryl esters and triglycerides form a hydrophobic core, whereas amphipathic phospholipids and free cholesterol form a surface monolayer and surround a core. The approximate number of molecules of phospholipids, free cholesterol, cholesteryl esters, and triglycerides are 700, 600, 1600, and 100, respectively, per LDL particle.⁹⁵ On average, 2700 molecules of fatty acids are bound in the different classes of lipids, of which about half are PUFA, linoleic acid being the major PUFA with smaller amount of arachidonic acid. Linoleic acid is predominantly bound in cholesteryl esters, whereas more arachidonic acid is bound in phospholipids than in cholesteryl esters. PC is the major phospholipid in human LDL particle.

The oxidation of LDL *in vitro* has been studied quite extensively using metal ions such as iron and copper, cells, azo free radical initiators, and enzymes such as LOX and CYP. The LPO in LDL particles proceeds by substantially the same mechanisms as in homogeneous solution described above. The free-radical-mediated oxidation of human LDL isolated from plasma gives cholesteryl ester hydroperoxides and PC hydroperoxides as major primary products. More cholesteryl ester hydroperoxides are formed than PC hydroperoxides. The relative susceptibility of fatty acid esters increases with increasing number of double bond. Cholesterol is oxidized appreciably only at the later stage. On the other hand, various secondary oxidation products of phospholipids and cholesterol are found in human LDL.⁹⁶ LPO products, above all reactive α,β -unsaturated aldehydes, modify apolipoprotein B100 covering LDL particle and make oxidized LDL pro-atherogenic.

HDL is capable of inhibiting oxidation of LDL and reducing cholesterol level, but HDL is oxidized similarly, resulting in loss of its anti-atherogenic function.⁹⁷

4.2 Oxidation of Plasma

Plasma is a suitable substrate for investigating the mechanisms, dynamics, and inhibition of LPO in biological settings. Lipids are present predominantly within lipoproteins in plasma together with various proteins, enzymes, and antioxidants. The free-radical-mediated oxidation of human plasma gives cholesteryl ester hydroperoxides as a major product together with minor amounts of cholesteryl ester hydroxides, PC hydroperoxides, and hydroxides. An example of plasma oxidation is shown in Figure 1.⁹⁸ Lipid hydroperoxides are reduced to the corresponding hydroxides by GPx. PC hydroperoxides are reduced faster than cholesteryl ester

hydroperoxides. The amounts of oxysterols are small.

The oxidation of plasma is a convenient system to elucidate the action mechanisms and protective effects of antioxidants in biologically relevant settings.^{98–100} The efficacy of both hydrophilic and lipophilic antioxidants and their interaction against LPO may be assessed in the oxidation of plasma induced by either hydrophilic or lipophilic azo initiator.

4.3 Lipid Peroxidation in Erythrocytes

Erythrocyte membrane is composed of cholesterol and various phospholipids. PUFA contained in the phospholipids are oxidized similarly to form various LPO products. The LPO of erythrocytes induces membrane damage and leakage of potassium ion, lactate dehydrogenase (LDH), and hemoglobin, eventually resulting in hemolysis.¹⁰¹ The radical-scavenging antioxidants such as vitamin E inhibit LPO and hemolysis.

4.4 Lipid Peroxidation in Experimental Animals

Animals have been used extensively to elucidate the mechanisms and products of LPO *in vivo* and also the biological effects of antioxidants against LPO. The LPO has been induced by γ -ray irradiation, photo-oxidation, hyperbaric oxygen, and administration of metal, carbon tetrachloride, or azo-compound. It was reported that administration of carbon tetrachloride to a rat induced a pronounced increase in the trans,trans-conjugated diene, a footprint of radical-mediated LPO, in microsomal lipid extracts and that the formation of trans,trans-isomers was strongly suppressed by prior administration of vitamin E.¹⁰² The administration of azo radical initiator to mouse induces oxidative stress¹⁰³ and increases the levels of LPO products such as hydroxyoctadecadienoic acid (HODE), HETE, and 8-IsoPs in plasma and tissues,¹⁰⁴ which are suppressed by radical-scavenging antioxidants.

5 PHYSIOLOGICAL LEVELS OF LPO PRODUCTS IN HUMAN

As shown above, LPO produces vast variety of products by different mechanisms and it is quite difficult to identify and quantify all of them. Furthermore, these products undergo secondary reactions and they are readily metabolized and excreted by efficient defense mechanisms *in vivo*. Therefore, the levels of LPO products measured in biological fluids and tissues reflect the balance between formation, metabolism, clearance, and excretion. Further, the diet contains various LPO products and the measurement of LPO levels in biological samples, especially plasma, may be confounded by the diet unless the subjects are fasted.¹⁰⁵ The measurement of the levels of LPO products in biological fluids and tissues is important to assess the extent of oxidative stress *in vivo*, to understand their physiological effects, and to evaluate the effect of antioxidants.

Lipid hydroperoxides, the primary products of LPO, are substrate of GPx¹⁰⁶ and selenoprotein P,¹⁰⁷ which reduce hydroperoxides to the corresponding hydroxides. GPx isotypes exhibit striking differences in peroxide reactivity.¹⁰⁸ Classical cellular GPx, GPx1, reduces hydrogen peroxide and free fatty acid hydroperoxides, but it does not reduce ester forms of lipid hydroperoxides nor cholesterol hydroperoxide. The type 4 GPx, also known as phospholipid hydroperoxide glutathione peroxidase (PHGPx) can catalyze the direct reduction of phospholipid hydroperoxides, cholesteryl ester hydroperoxides, and cholesteryl hydroperoxide. Recent study showed 25-fold greater activity of phospholipid hydroperoxides toward GPx4 than 7 α -OOHCh.¹⁰⁹

Metabolism and excretion are important factors that determine physiological levels of LPO products *in vivo*. They are not as extensively studied nor elucidated as the formation of LPO products. Incubation of PCOOH in human plasma gave the corresponding PCOH with minor amounts of the corresponding cholesteryl ester hydroperoxides and hydroxides, which were formed by the action of lecithin cholesterol acyltransferase (LCAT) present in HDL.¹¹⁰ Disposition, biotransformation, and clearance of exogenously prepared, radiolabeled LPO products have been studied in animal experiments.¹¹¹ Although it has to be taken into consideration that the metabolic pattern of exogenously

administered LPO products may be different from that of endogenously formed products, such studies must be useful to shed light on the fate of LPO products *in vivo*. The major metabolic pathways involve hydrolysis by phospholipases, conjugation by glutathione *S*-transferases, and β -oxidation, in addition to the reduction mentioned above.

LPO products in human fluids and tissues have been measured by diverse methods and techniques.¹⁰⁵ Recently, the LPO products have been analyzed extensively by gas chromatography-mass spectrometry (GC-MS) and liquid chromatography-tandem mass spectrometry (LC-MS/MS), which enabled analyses with high sensitivity and specificity, although it is labor intensive and high expenditure.¹¹² One advantage of LC-MS/MS methods is that the sample preparation for analysis is simpler than that for GC-MS because no derivatization is required. In some cases, the biological samples are treated with triphenylphosphine to reduce peroxides and/or hydrolyzed to convert fatty acid esters and cholesteryl esters to free fatty acid and free cholesterol forms, respectively. Recently, the levels of LPO products in biological fluids and tissues have been measured extensively as potential biomarkers for oxidative stress *in vivo*.^{105,113,114}

5.1 Lipid Hydroperoxides

Hydroperoxides are the major primary products of free-radical-mediated LPO of PUFAs and cholesterol and their levels in human blood have been measured in many studies by several methods including high performance liquid chromatography (HPLC)-chemiluminescence and LC-MS. The reported levels of phosphatidylcholine hydroperoxides (PCOOH) in healthy human plasma range from nil to 220 nM, while cholesteryl ester hydroperoxides (CEOOH) from nil to 12 nM,¹ except one report in which 497 nM was detected by HPLC-chemiluminescence method.¹¹⁵ Lipid hydroperoxides measured by FOX2 assay have been reported to be much higher, for example, 2.8 μ M in plasma of healthy subjects.¹¹⁶ It has been reported that lipid hydroperoxides levels are elevated in diseased patients, such as hyperlipidemia, atherosclerosis, diabetes mellitus, hemodialysis, stroke, multiple sclerosis, subarachnoid hemorrhage, and alcoholic patients.

5.2 Thiobarbituric Acid Reactive Substances (TBARS)

Thiobarbituric acid reactive substances (TBARS) and MDA have been used as a biomarker of LPO for more than 30 years.¹¹⁷ Although these markers are frequently used in many laboratories due to simplicity and low cost, the validity of these markers has been criticized often for a lack of specificity and problems with post-sampling formation. TBARS was measured originally by spectrophotometric detection, but recently MDA–TBA adducts are measured by HPLC with UV/Vis or fluorescence detection and MDA is measured also by GC-MS after derivatization. The reported values for MDA in human plasma are often higher than 1 μM .¹¹⁷

5.3 Isoprostane (IsoP)

As described above, IsoPs are a series of prostaglandin-like compounds produced by the free-radical-mediated oxidation of arachidonic acid independent of COX.⁶⁸ IsoPs are accepted as the most reliable biomarker of oxidative stress *in vivo* and many studies show that the levels of IsoPs in human plasma and urine are increased in a number of diseases.^{118,119} The physiological level of IsoPs in human plasma is around 1 nM, which is much lower than those of HETE and HODE.

5.4 Aldehydes

Many types of aldehydes have been detected in human fluids and tissues. The HNE levels in human samples have been measured by various methods in free and adduct forms.⁶⁹ HNE was measured as a trimethylsilyl ether of pentafluorobenzyl oxime by gas chromatography negative ion chemical ionization mass spectrometry using selected-ion monitoring in 194 healthy men and women and it was 74 nM, increasing with age.⁶⁰ Some studies reported higher values such as 660 nM in plasma of healthy adults¹²⁰ and 300 nM in umbilical cord plasma of full-term healthy neonates.¹²¹ The HNE levels in plasma and cerebrospinal fluid of Alzheimer's disease patients¹²²

and plasma of major depression patients¹²³ were reported to be higher than those of controls. As mentioned above, the levels of MDA in human plasma are reported to be higher than 1 μM ,¹¹⁸ but these values may not reflect the LPO level accurately.

5.5 Nitro-Fatty Acids

Nitro-fatty acids have been found in human plasma. The basal plasma concentrations of 9- and 10-nitro-oleic acids in healthy subjects were reported by Baker *et al.*⁷⁵ as 619 nM (free forms) and 302 nM (ester forms) as measured by LC-MS/MS and those in erythrocytes were 50 and 199 nM, respectively. The levels of nitro-linoleic acids were lower than nitro-oleic acids.^{75,76} On the other hand, much lower levels of nitro-oleic acids were reported, at a mean concentration of 1 nM measured by GC-MS/MS.¹²⁴

5.6 Oxysterols

Ring- and side-chain oxidation products of cholesterol in human plasma have been measured in many studies. Hydroperoxide is the primary product of cholesterol oxidation by free radicals and singlet oxygen. 7-Hydroperoxycholesterol **12** has been detected in human atherosclerotic lesions,¹²⁵ erythrocytes,^{126,127} lung and kidney,¹²⁸ and alcoholic fatty liver, but not in control and alcoholic cirrhotic liver.¹²⁹ It was reported that **12** was the major oxidation product in the early stage but readily metabolized and only trace amounts could be detected in human atherosclerotic plaque.¹³⁰ 5-Hydroperoxycholesterol **10**, a specific product of singlet oxygen oxidation, was detected in human and rat skin and found to increase with sunlight exposure.^{131,132}

More data are available for 7-oxygenated oxysterols. 7 α -Hydroxycholesterol **9** is formed by both enzymatic and nonenzymatic mechanisms, whereas 7 β -OHCh and 7-KCh **14** are formed mainly by free-radical-mediated oxidation. The sum of 7 β -OHCh and 7-KCh **14** ranges between 26 and 63 nM and higher levels have been observed in many diseased patients.^{1,130,133–136}

Table 5 Hydroxyoctadecadienoic acid (HODE) and 7-hydroxycholesterol (7-OHCh) in human blood.

	HODE (nM)	18:2 (mM)	7-OHCh (nM)	Ch (mM)	HODE/18:2 ($\mu\text{mol mol}^{-1}$)	7-OHCh/Ch ($\mu\text{mol mol}^{-1}$)	(HODE/18:2)/ (7-OHCh/Ch)
Plasma	203	1.28	243	6.87	194	40.9	4.74
RBC	1919	0.66	5226	11.0	3519	686	5.13
Plasma/RBC	1/9.4	—	1/21.5	—	1/18.1	1/16.8	

Source: Adapted from Ref. 133.

^aThe levels are the average values obtained for plasma and erythrocytes (RBC) from 44 healthy human subjects after reduction and saponification. HODE is a sum of free and ester forms of four isomeric hydroxyoctadecadienoic acid. 7-OHCh is a sum of free and ester forms of 7α - and 7β -hydroxycholesterol. 18:2 and Ch are the sum of free and ester forms of linoleic acid and cholesterol, respectively.

5.7 Oxidation Product/Parent Lipid Ratio

The ratio of oxidation product to parent lipid is another biomarker to show the level of oxidative stress *in vivo*. In some studies, the biological fluids were reduced by sodium borohydride or triphenylphosphine and saponified with potassium hydroxide to convert hydroperoxides and ketones as well as hydroxides of free and ester forms of fatty acids and cholesterol to hydroxyfatty acids and hydroxycholesterol, respectively. The levels of HODE and 7-OHCh thus obtained for human plasma and erythrocytes are summarized in Table 5 together with the total concentrations of linoleic acids and cholesterol.¹³³ The relative extent of oxidation of linoleates to that of cholesterol as estimated from the ratio (HODE/18:2)/(7-OHCh/Ch) is calculated to be 4.7 and 5.1 for plasma and erythrocytes, respectively. The relative extent of LPO in plasma to that in erythrocytes is estimated to be 1/9.4, 1/21.5, 1/18.1, and 1/16.8 from HODE, 7-OHCh, HODE/18:2, and 7-OHCh/Ch, respectively, suggesting that both linoleates and cholesterol are relatively more oxidized in erythrocytes than in plasma of healthy humans.

The ratios of 7-oxygenated oxysterols to cholesterol calculated from the reported literature values range from 7.6 to 41 μmol for healthy human plasma, while higher ratio for normal artery and much higher ratio for atherosclerotic lesion, but not exceeding 1% of cholesterol, were observed.^{126,134–136} It was also reported that the levels of 7-KCh **14** were 99.4 and 383 nM in plasma and erythrocytes, respectively, from healthy human subjects.¹³⁷

The oxidation status of LDL isolated from healthy human plasma was assessed by HODE, 7-OHCh, and 8-IsoP after fractionation with anion-exchange HPLC.¹³⁸ Human LDL was subfractionated as

LDL-1, LDL-2, and LDL-3 in the order of increasing anion charge of LDL particles. Each fraction accounted for 75.1, 19.3, and 5.6% of total LDL respectively. The levels of HODE, 8-IsoP, and 7-OHCh in each LDL fraction are summarized in Table 6, together with the ratio to the respective parent lipids. It clearly shows that the levels of HODE, 8-IsoP, and 7-OHCh and their ratio to parent lipids all increased with an increase in anion charge of LDL particles, the highest ratio being 3.67 molecules HODE/1000 molecules linoleates, 0.367%. The smaller ratio of 8-IsoP/20:4 is ascribed to the fact that 8-IsoP is one of the many products of arachidonate oxidation. It also shows that linoleates and arachidonates are relatively more oxidized than cholesterol with increasing oxidation of LDL. In addition, the LPO in HDL has received attention in connection with atherosclerosis.¹³⁹

Although numerous studies have reported the levels of LPO products in human subjects, only a few papers measured products from linoleates, arachidonates, and cholesterol simultaneously from the same samples.^{113,133} It is difficult to define the reference levels of LPO products, partly because the reported values vary considerably, which is not surprising since they are affected by many factors such as lifestyle including diet, drinking, smoking, and exercise. In Table 7, the levels

Table 6 Lipid peroxidation products in human LDL fractions.

LDL fraction	HODE	8-IsoP	7-OHCh
LDL1	1935 (227)	5.8 (8.7)	2100 (116)
LDL2	4657 (782)	33.1 (18.3)	5703 (181)
LDL3	36434 (3670)	162.1 (66.6)	18314 (344)

Table 7 Estimated levels of free-radical-mediated LPO products in human plasma.^a

LPO products	nM	μM/M parent lipid
F ₂ -isoprostanes	1	10
Total HETE ^b	100	450
9- and 13-(<i>trans,trans</i>)-HODE	130	100
7β-OHCh	10–20	2–4
7-KCh	20–30	6

^a Adapted from Ref. 1. © 2009, Elsevier B.V.^b Enzyme-mediated oxidation products may be involved.

of free-radical-mediated LPO products in healthy human plasma estimated from literatures are summarized. Among them, the level of HETE may contain those produced by enzyme oxidation. It may be said that the level of LPO products in the plasma of healthy human subjects is below 1 μM and 0.1% of parent lipids.

One of the interesting points is the unexpectedly high levels of oxysterols observed in human plasma, LDL, and erythrocytes. In contrast to PUFAs, cholesterol does not contain bisallylic hydrogen and the reactivity of allylic hydrogen toward peroxy radical, a chain-carrying species in LPO, is about 100 times smaller than that of bisallylic hydrogen (Table 2). In fact, it was found that little oxidation of cholesterol proceeded in the oxidation of isolated LDL *in vitro* and it was oxidized after substantially all PUFAs were consumed.⁴⁷ It may be noted that cholesterol was relatively more oxidized than linoleates in the cultured cells under oxidative stress induced by selenium deficiency and free radical attack.⁸² The high level of 7-oxygenated oxysterols observed in healthy human blood may be ascribed to slower metabolism and/or excretion and to enzymatic oxidation by 7α-hydroxylase, CYP7A1.

Finally, it should be noted that, as often pointed out, accurate determination of LPO products in human samples is not easy and great care should be taken in the measurement and interpretation of the data. A potential generation or loss of LPO products during sampling, storage, extraction, isolation, and analysis may take place. The plasma contains several millimoles of reactive lipids and the oxidation of 0.01% gives several hundreds of nanomoles, suggesting the difficulty of accurate measurement. Sodium borohydride used as a reducing agent may induce *ex vivo* oxidation, especially in the presence of metals such as iron contained

in blood and tissues, which is avoided by using triphenylphosphine as a reducing agent.¹⁴⁰ The use of appropriate internal standard is recommended. Furthermore, as mentioned above, blood should be withdrawn after sufficient fasting.

6 BIOLOGICAL EFFECTS OF LPO PRODUCTS

6.1 Cytotoxic and Cytoprotective Effects of LPO Products

It has been shown that LPO products exert various biological effects either directly by reacting with proteins, enzymes, and nucleic acids or indirectly through receptor-mediated pathways.^{12–14,62,80,141–143} LPO alters chemical characteristics and physical organization of cellular membranes to induce functional loss and modifies lipoproteins to pro-atherogenic and pro-inflammatory forms. LPO products are assumed to be pathogenic and contribute to the etiology of various diseases, including neurodegenerative diseases.¹⁴⁴ Aldehydes react with nucleic acid bases to give exocyclic adducts with a five-membered ring (etheno adducts) and a six-membered ring (propane adducts), which are accepted to contribute to the mutagenic and carcinogenic effects associated with oxidative stress.^{145,146} Oxidative modification of nucleic acids has also been implicated in neurodegeneration.^{147–149}

It is known that LPO products, both chemically reactive and stable compounds, exert cytotoxic effects. Unsaturated carbonyl compounds, lipid hydroperoxides, hydroxyl-fatty acids, hydroxy-cholesterols, ketocholesterol, epoxycholesterol, and lyso PC all induce cell death.¹⁵⁰ At the same time, it has been shown over recent years that LPO products at low concentrations activate the cellular cytoprotective signaling pathways and increase antioxidant defense capacity.¹⁵¹ It is becoming increasingly clear that the pretreatment of cells with LPO products such as PCOOH, lyso PC, hydroxycholesterol, epoxy cholesterol, HNE, and 15 d-PGJ₂ at sublethal level enhances the cell tolerance against forthcoming oxidative stress induced by ROS/RNS and LPO products.^{152–155} Another example is the effect of oxidized LDL. The association of oxidative modification of LDL and development of atherosclerosis has been recognized in many *in vitro* and

in vivo studies, but it has also been observed that low levels of oxidized LDL are cytoprotective and anti-atherogenic.^{14,156}

It may be said that the adaptive response induced by ROS/RNS, LPO products, and physical stimuli is a general phenomenon endowed inherently to aerobic organisms during evolution to cope with oxidative stress. The adaptive response to low levels of radiation has been known for many years as hormetic effects.¹⁵⁷ A human being is prepared to respond to the oxidative stress and capable of coping with it by inducing adaptive response to maintain homeostasis or even to stimulate ourselves to promote healthy state, both physically and emotionally.

6.2 LPO Products as Signaling Messenger

Many data show that ROS/RNS are used in physiological settings in a regulated manner.^{158,159} It is also assumed that LPO products modulate cell signaling and gene expression.¹ However, the experimental evidence was obtained mainly in the studies using cultured cells and the physiological significance of the action and role of free-radical-mediated LPO and its products as cellular signaling messenger *in vivo* is not clear. It should be added that, in order to exert physiologically important function as a regulator of gene expression and mediator of cellular signaling, the formation of LPO products must be tightly controlled and programmed. It may be possible to regulate the formation of superoxide, hydrogen peroxide, and NO and also enzymatic LPO,¹⁶⁰ but it seems difficult to program and control the time, site, and amount of free radical formation, the selectivity and specificity of free-radical-mediated LPO reactions, and the formation of LPO products.

7 CONCLUDING REMARKS

There is no doubt that free radicals induce LPO *in vivo* and that LPO and its products exert deleterious effects, although LPO products may play a role as a cellular regulator and signaling messenger under certain cases. Numerous studies show the cytotoxicity of LPO products, and an association between the increase in the levels of LPO products

and the progress of oxidative stress-related diseases, although it is not clear whether LPO is important as a cause or it is simply a consequence.

In any case, it is surmised that the aerobic organisms have created a fine defense network and sophisticated response system during the course of evolution to cope with, or even utilize, the moderate level of LPO, but that excessive unregulated LPO leads to degenerative and pathological consequences and, in such cases, the radical-scavenging antioxidants should exert beneficial effects. Many issues have been elucidated on LPO in the last three decades, but as many issues still remain unanswered or emerged and await to be addressed in the future studies.

Lipid Isomerization

Carla Ferreri and Chrysostomos Chatgililoglu

ISOF, Consiglio Nazionale delle Ricerche, Bologna, Italy

1 INTRODUCTION

Free radical chemistry of lipid molecules is very well known in the field of oxidative processes. This subject is fully addressed in the article **Lipid Peroxidation**. Only in the end of twentieth century free radical reactivity involving directly the double bonds of unsaturated fatty acids started to attract interest with the process of lipid isomerization. Actually, the cis–trans isomerization of double bonds was known in free radical chemistry much earlier by the work of Walling in 1957,¹ but never applied to unsaturated fatty acids in an aqueous environment.^{2–4}

The interest in lipid isomerization resulted very timely in the development of chemical biology. In fact, considering that in eukaryotic cells the natural fatty acids have mainly the cis configuration, the formation of trans isomers can be studied not only as a free radical-mediated chemical conversion but also as an important structural change in connection with a cellular stress or signal. Fatty acid residues are present in several biologically important lipid molecules, such as triglycerides and phospholipids. Fatty acids are carboxylic acids having a long hydrocarbon chain (up to 26 carbon atoms), which can be saturated or unsaturated with up to six double bonds. They have important roles in biology, in particular for the regulation of the structure and functions of the cell membrane compartment, including permeability and fluidity properties. The geometry of the double bonds in naturally occurring

mono- and polyunsaturated fatty acid (MUFA and PUFA) residues is crucial for this regulation.

Examples of MUFA and PUFA structures and also of some trans isomers are shown in Figure 1, with the common names and the abbreviations describing the position and geometry of the double bonds (e.g., 9*cis* or 9*trans*) as well as the notation of the carbon chain length and total number of unsaturations (e.g., C18:1).⁵

The cis geometry is strictly controlled by the regiospecific and stereoselective enzymatic activity of desaturases during MUFA and PUFA biosynthesis.⁶ This choice of nature is interesting, considering the different stability of the two geometrical isomers and the fact that the thermodynamically less stable cis form is the ubiquitous one. Therefore, the role of geometry in living system is an interesting research subject, and in particular, the isomerization by free radical species can be studied not only from the chemical point of view but also more in general as the loss of a structural information needed for biological activities.

It is also worth noting that the discovery of the lipid isomerization process gave a different perspective to the previously known detection of trans fatty acid isomers in humans, thought to derive only from dietary sources. In fact, in the past years, a series of panels made in several countries determined that the increase in trans fatty acid isomers in humans derives from the consumption of deodorized and partially hydrogenated fats and oils contained in foods.^{7,8} Chemically speaking, these processes can cause the formation of different products, either

Figure 1 Examples of natural fatty acids and some trans isomers.

geometrical and positional isomers of the natural substrate. Public concern arose due to the harmful effects of trans fatty acids on health, involving risk factors of heart attack and coronary artery disease, impairment of fetal and infant growth, and inhibition of lipid metabolic pathways.^{9–12} Nowadays, different molecular libraries can assist either the dietary and the endogenous trans fatty acid isomer detection, thus distinguishing among different contributions.

The lipid isomerization offers a beautiful example of a cross-disciplinary research subject, involving several life science disciplines with the centrality of free radical chemistry. The multiple aspects of these subjects have been time to time summarized in articles and reviews.^{13–18} This article aims at

offering an overview, starting from the chemical mechanisms and applications of supramolecular systems such as liposomes, and including the meaning of lipid isomerization as a free radical signal or damage in a biological environment. The readers will appreciate the various fields where the isomerization process has been applied and its future perspectives.

2 FREE RADICAL MECHANISM OF LIPID ISOMERIZATION

The reactivity of the double bond toward free radicals is well known, being many free radicals

(e.g., $\text{RS}^\bullet$, $\text{RSe}^\bullet$, $\text{RSO}_2^\bullet$, $\text{NO}_2^\bullet$, $\text{R}_3\text{Sn}^\bullet$, $(\text{Me}_3\text{Si})_3\text{Si}^\bullet$, etc.) and atoms (e.g., $\text{Br}^\bullet$, $\text{I}^\bullet$, etc.) able to add reversibly to this functionality. Among them, the potential of S- and N-centered radicals emerged for their biological significance in the propagation of free radical stress.

Scheme 1 shows the process where the radical species $\text{X}^\bullet$ adds to the cis or trans double bonds, thus forming a radical adduct that ejects the radical and reconstitutes the double bond.^{1–4,19}

During this process, the isomeric purity is lost since the unsaturated substrate becomes a mixture, reaching about an 80:20 trans:cis ratio, regulated by thermodynamical factors. The efficiency of the isomerization process strongly depends on the characteristics of the attacking radicals, and it was noted that thiyl radicals ($\text{RS}^\bullet$) are very effective in this transformation.²⁰

There are two features of the free radical isomerization that should be evidenced also for their relationships with the biological process: (i) all steps are reversible and the overall process is catalytic; provided that the free radical intermediate is not trapped before the β -elimination, one radical is able to sustain the catalytic chain, isomerizing a number of molecules before going to the termination step. This results in an amplification of the damaging potential at low levels of radical generation; (ii) only geometrical isomers can be obtained after isomerization, since no positional shift of the double bond can occur during the addition–elimination process. This is a very important feature for building molecular libraries related to geometrical isomers as free radical stress biomarkers, also in view of the fact that different trans isomers (positional) can derive from dietary sources.

Among the radical species, S-centered radicals are most specific and efficient to sustain catalytic cycles of lipid geometrical isomerization; therefore, they can be proposed as the real culprits of the biologically occurring process,²¹ whereas for N-centered radicals, there are some confounding aspects that are further detailed.

2.1 Thiyl Radicals as Isomerizing Agents

Lipid isomerization is successfully obtained by S-centered radicals, which can be generated from a variety of compounds including thiols, disulfides, and, under certain conditions, thioethers. Using thiols as the starting reagent, the “classical” free radical initiation by azocompounds in alcoholic solutions was used to study MUFA residues in alcohol solution, thus obtaining basic chemical and kinetic information. Under catalytic thiol concentrations (<50 mol% equiv relative to the fatty acids), the isomerization process is easily achieved in quantitative yield, leading to the formation of >80% of trans isomers. The process is independent from the position of the double bond and is equally efficient for different MUFA.²²

The MUFA experiments allowed the rate constants of each step to be obtained, using different initiation procedures including photolysis.^{23,24} The addition rate constants k_a to cis and trans isomers were almost similar ($k_a^{\text{cis}}/k_a^{\text{trans}} = 1.8$), whereas the unimolecular β -elimination rate constant (k_f) for the formation of the trans isomer was one order of magnitude faster ($k_f^{\text{cis}}/k_f^{\text{trans}} = 9.4$). The large preference of fragmentation to the trans isomer was attributed to different energy barriers for the formation of the two transition states.²³ These data allowed to define that the formation of trans isomers is favored not only by thermodynamic reasons but also by kinetic factors of the fragmentation step; moreover, the fragmentation step results to be very fast ($k_f^{\text{trans}} = 1.6 \times 10^8 \text{ s}^{-1}$), and this can be important in the estimation of competitive processes. In fact, the intermediate radical in Scheme 1 can be trapped either by oxygen or H-donors. Both these reactions can occur in a biological environment and the kinetic data of the β -elimination step are necessary to estimate the occurrence of alternative pathways. It is also worth adding that thiols are also well known in biology as “repairing” agents for free radical damage, due to their good H-donor ability. Therefore, the fate of the thiol reactivity and the

Scheme 1 The addition–elimination steps of free radical-catalyzed cis–trans isomerization of double bonds.

extent of the isomerization process make part of a wide scenario where several possibilities have to be evaluated.

The kinetic data allowed a realistic context of the lipid isomerization to be formulated. In Section 4, the role of oxygen and antioxidants is considered in the whole process. By these preliminary evaluations, lipid isomerization appeared to be a feasible conversion to occur in a biological environment.

The isomerization was tested also as a synthetic access to trans phospholipids. 1-Palmitoyl-2-oleoyl phosphatidyl choline (POPC) was converted to a 17:83 mixture of POPC:1-palmitoyl-2-elaidoyl phosphatidyl choline (PEPC) in 99% yield in the presence of catalytic amount of 2-mercaptoethanol under photolytic conditions, as shown in Scheme 2.²⁵

It is worth mentioning that this synthesis also allowed to gather data for the first time on the behavior of trans lipids in the spontaneous formation of liposome vesicles and the role of trans lipids in membrane behavior.^{25,26} This is a very interesting subject also for the field of archeobiology, studying early life on Earth and the formation of the first cellular entity. Provided that lipids gave the membrane aggregation for the birth of the first cell, it is worth underlining that the cis geometry should have not been prevalent in the environment that accompanied the early life development, due to high radiations and temperatures. Therefore, the experimental protocols related to the studies

of the behavior of proto-cells should take into account the trans geometrical features. Interestingly, comparison of different vesicles generated spontaneously from phospholipids having saturated, cis-monounsaturated, and trans-monounsaturated residues evidenced that the dimension of the resulting cell compartment goes from smaller to larger following the order: saturated < *trans*-MUFA < *cis*-MUFA.²⁵ The cis geometry was highlighted as an important element for obtaining size of compartments larger than 100 nm. As a matter of fact, the dimension theory has recently proven that protein synthesis can start in 100-nm POPC vesicles enclosing an ensemble of enzymes, ribosomes, tRNA, and low molecular weight molecules.²⁷ The easy synthetic access to trans phospholipids can be useful for a thorough study on mixtures of different geometrical fatty acid structures in the biological membranes.

In case of PUFA residues, the isomerization leads to several isomers calculated as 2^n , n being the number of double bonds. The process occurs by a step-by-step procedure depicted in Scheme 3 with the mono-trans isomers as the first products.²⁸

The formation of di-trans isomers can occur in a subsequent step, in particular, when the mono-trans isomer concentration increases in the medium. This leads to the possibility of stopping the isomerization procedure at different stages, with enrichment of the desired isomer fraction for an easy isolation procedure. Therefore, the thiol radical-catalyzed process can be suggested as the best synthetic way

Scheme 2 The conversion of POPC (1-palmitoyl-2-oleoyl phosphatidyl choline) to PEPC.

Scheme 3 The step-by-step isomerization of polyunsaturated substrates.

to build-up a library of geometrical isomers to be used in the recognition of the trans isomer presence in naturally occurring materials. Instead, other lipid isomerization procedures, such as heating^{29–31} or acid/base treatment,³² can afford geometrical and positional isomers, which are complicated to resolve especially in case of PUFA substrates. The recognition of trans lipids will be further treated in Section 3.2.

In PUFAs, the exhaustive isomerization of the double bonds brings to the formation of all-trans compounds, which can be used for the study on the biological consequences of the total loss of the cis geometry, thus representing an anti-sense strategy. In fact, biological activities are linked to all-cis PUFA structures and the synthesis of all-trans arachidonic acid (AA), linolelaidic acid, all-trans arachidonoyl ethanolamide (all-trans anandamide), and linolelaidoyl ethanolamide allowed the effects given by the change in the geometrical asset to be studied for the first time.^{33,34} The structures are shown in Figure 2.

Some interesting observations can result. For example, the isomer of AA gave a dual effect on platelets.³³ At high concentrations ($>10^{-4}$ M), all-trans AA caused aggregation, while the respective natural isomer have similar effect at approximately 10 times lower concentration. On the other hand, at lower concentrations, all-trans AA inhibited the aggregation induced by the strong platelet agonist, platelet activating factor, PAF (4×10^{-10} M) with an $IC_{50} \sim 6 \mu\text{M}$ but not that induced by thrombin. Similar results were obtained with all-trans isomer of linoleic acid.

Figure 2 All trans lipid strategy with all-trans arachidonic acid, all-trans anandamide, linolelaidic acid, and linolelaidoyl ethanolamide.

The anti-sense strategy carried with all-trans lipids indicated that the effects obtained by such structural change are not completely adverse with the pathways followed by their (natural) cis counterparts, although the interaction with the enzymatic cascades can be much weaker.

The synthetic isomerization procedure was also applied to natural triglycerides that make part of the trans lipid library.³⁵ In Table 1, the treatment

of oils containing MUFA and PUFA residues with the isomerization procedure is shown. The enrichment of trans isomers is obtained after applying the winterization procedure, which consists of the low temperature (-20°C) crystallization in a suitable solvent. In this work, the effect of lipase-catalyzed transesterification procedures was also tested (*Candida antarctica* lipase), realizing that hydrolytic enzymes can function with cis and trans substrates without distinction. This raises an interesting question on specific enzymatic systems able to recognize the presence of trans isomers in eukaryotes, which still waits for an answer. In Section 4.3, it will be shown that the enzymatic cis–trans conversion in prokaryotes is an important subject of research. The oil isomerization is relevant for the biotechnological area of food industries, which has been extensively treated in books and papers addressing the quality and quantity of trans isomers produced in the oil processing.^{7,8,36–39}

As far as S-containing compounds used for thiyl radical generation are concerned, most of the synthetic procedures and kinetic studies were carried out with 2-mercaptoethanol as the thiol. This is an amphiphilic thiol, highly soluble in hydrophobic and hydrophilic solvents, which is also useful for the efficiency and flexibility of the reaction. The synthetic procedure works with a variety of free radical conditions and thiols, as well as S-containing compounds, including sulfonfyl species.⁴⁰ Being sulfur-containing compounds

relevant in biological systems, the chemical/kinetic observations should be easily transferred from a synthetic to a biomimetic model. In this respect, 2-mercaptoethanol turned out to be very useful for exchanging information from one system to another.

In heterogeneous systems such as liposomes, further treated in this article, an additional role is played by the partition coefficient of the reactive species in the medium, making differences among the different biologically relevant S-containing compounds.

2.2 Nitrogen-Centered Radicals as Isomerizing Agents

Other radicals and atoms are able to induce cis–trans isomerization following the mechanism reported in Scheme 1. $\text{NO}_2^{\bullet}$ radicals are known isomerizing agents from the work by Titov in 1963.⁴¹ From a biological point of view, N-centered radicals can be interesting since they make part of the nitrosative stress with damaging potential to biomolecules.^{42–44} There are a few kinetic data for the reaction of $\text{NO}_2^{\bullet}$ radicals with olefins, indicating that both the addition and the hydrogen abstraction steps are slow processes.⁴⁵ For the addition of $\text{NO}_2^{\bullet}$ radicals to 2-pentene, the addition rate constants are slow ($k_a^{\text{cis}} = 0.18$ and $k_a^{\text{trans}} = 0.038 \text{ M}^{-1} \text{ s}^{-1}$) and the fragmentation step occurs with $k_f = 8 \times 10^4 \text{ s}^{-1}$ for both isomers. Moreover, the H-abstraction from bisallylic position also showed to be competitive with addition in solution.⁴⁵ Therefore, the result of $\text{NO}_2^{\bullet}$ radical reactivity can be a mixture among addition, isomerization, and oxidation depending on the reaction conditions. The reaction with methyl linoleate has been studied in detail,⁴⁶ individuating that $\text{NO}_2^{\bullet}$ radicals can initiate lipid autoxidation due to the bisallylic H abstraction. A small yield of trans isomers can also derive from the reversible addition but only in the absence of oxygen. It can be estimated that in the presence of 0.1 mM oxygen, the isomerization becomes unimportant due to the trapping of the adduct radical and formation of peroxy derivatives, which evolve toward oxidation products.⁴⁷

$\text{NO}_2^{\bullet}$ radical isomerization has been proposed as a process occurring in the biological environment, envisaging its involvement in the formation of

trans AA in platelets⁴⁸ as well as in the general vascular stress.⁴⁹ Although the direct reaction of NO₂[•] radicals with methyl arachidonate can give rise to some trans isomers, this process has to be contextualized in an *in vivo* situation where all competitive pathways can occur. As a premise to any reactivity evaluation, it must be underlined that the prediction of a free radical biological pathway is possible by a careful evaluation of the rate constants of all possible processes and the relative concentration of all reaction partners. As it will be further detailed in the sections dedicated to biomimetic studies, free radical chemistry is quite predictable based on the known kinetic and thermodynamic data, but in the biological environment, other factors must be taken into account: the system is heterogeneous, and the partition coefficient as well as other parameters, such as the diffusibility of the reaction partners, are all important for the reaction outcomes.

In case of NO₂[•] radicals, it is well known that they react quite fast at physiological pH with thiols, such as glutathione ($k = 3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$), also being a moderate one-electron oxidant $E^0(\text{NO}_2^{\bullet}/\text{NO}_2^-) = 1.04 \text{ V}$ (vs NHE). Both thiyl and NO₂[•] radicals react with urate at a similar rate ($k \approx 10^7 \text{ M}^{-1} \text{ s}^{-1}$).^{50,51} By taking into account the relative concentrations in different compartments, it can be estimated that the lifetime of NO₂[•] radicals in cytosol is <10 μs and that thiols are the dominant sink for NO₂[•] radicals in cells and tissues, whereas urate is the main scavenger in plasma. This reactivity is obviously influenced by the pK_a of the different thiol compounds, but it can be generally said that thiols act as anti-nitrosative agents.⁵²

As a result of all these considerations, thiyl radicals emerge as the main isomerizing agent in a biological system and the role of N-centered radicals is more likely to mediate thiyl radical formation rather than cause directly a cis–trans lipid isomerization.

2.3 Degradative Processes Involving Sulfur-Containing Compounds

Lipid isomerization became an interesting subject of chemical biology due to its relationship with the free radical reactivity of biologically relevant S-containing compounds. They can produce thiyl

radicals by two main pathways: (i) the H-atom donation from thiol compounds as well as the bond breakage from disulfides, both making part of important protective and redox systems in the cell⁵³ and (ii) desulfurization (elimination) processes from reactive intermediates during stress.^{4,21} In both cases after generation of thiyl radicals, lipid isomerization can occur, the two processes making part of a tandem damage, as described in Sections 2.3.1 and 2.3.2. This was also thought to be the mechanistic scheme followed by lipid isomerization *in vivo*.

Before lipid isomerization came into play, the scenario of the damage to cysteine (CySH), cystine (CySSCy), and methionine (Met)^{54,55} was connected mainly to a direct oxidative stress. The reactivity of these biologically relevant sulfur compounds under free radical conditions is treated in the article **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**. Here, it is important to underline that in biology, thiols are mostly perceived as protecting agents for free radical stress, being glutathione one of the most important free radical trapping agents, and the role of disulfides connected with the equilibrium between the oxidized and the reduced forms.^{51,53} In fact, thiols and disulfides are not perceived as possible damaging agents to biomolecules, although mechanisms of thiyl radical generation and reactivity have been proposed.^{56–58} This is an example of information gap between chemistry and biology, which has to be addressed by improving interdisciplinarity.

Lipid isomerization can be utilized as a nice example of a chemical mechanism transferred to biology for a better understanding of the puzzling scenario of free radical stress and the related products.

2.3.1 The Case of S-Containing Amino Acids and Peptides

H-atom abstraction from thiols is very well known as “repair reaction,” which is quite important for protection of living systems. In this respect, protective agents can be either small molecules, such as glutathione,⁵⁹ or large structures, such as albumin.⁶⁰

Considering that biological environment is a heterogeneous system, it is worth recalling that thiyl radicals from CySH residues reside in the hydrophilic part, whereas CyS[•] radicals generated

Scheme 4 Pathways of formation of thiyl radicals from disulfides.

in peptides or proteins can instead be close to hydrophobic compartments, such as membrane lipid bilayers. The localization of sulfur residues is quite important in heterogeneous systems, and it will be more appreciated in liposomes, described in Section 3.

Disulfides can lead to the formation of thiyl radicals by different pathways shown in Scheme 4.⁶¹ It is worth mentioning that when disulfides are present in macromolecular structures, such as disulfide bridges in proteins, the corresponding thiyl radicals cannot behave as in small molecules (such as cystine or oxidized glutathione) and their localization, as well as partition, is restricted. This can also affect the reactivity toward lipid isomerization.

Several biomimetic studies in the field of amino acid damage and lipid isomerization have been performed using ionizing radiations. In water, the effect of ionizing sources such as ⁶⁰Co is to generate the primary water radicals and solvated electrons according to Figure 3.⁶²

Provided that a cobalt source is available, this initiation can be suggested as a simple protocol to simulate the effect of stress in the biological environment. Indeed, the initiation compartment is water and highly reactive species such as hydrated electrons (e_{aq}^-) and $\cdot\text{OH}$ radicals are produced in the system with several advantages: (i) the production of $\cdot\text{OH}$ radicals can occur without the presence of metals or oxidizing agents, which are instead needed in other protocols, such as the Fenton reaction; (ii) the selection of the reactive species

Figure 3 Formation of reactive species from the irradiation of water (radiation chemical yield).

can be simply affected, that is, by flushing of gases in the reaction medium: for example, e_{aq}^- can be quenched by flushing N_2O in the medium, leaving $\cdot\text{OH}$ radicals and $\text{H}^{\cdot}$ atoms as reactive species in a 90 and 10% relative distribution. N_2O efficiently reacts with electrons ($k = 9.1 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$); alternatively, hydrated electrons can be chosen as the main reactive species, mainly quenching $\cdot\text{OH}$ radicals by alcohols (i.e., by *t*-BuOH with $k = 6 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$); the reactivity of $\text{H}^{\cdot}$ atoms can be further selected, either by eliminating $\cdot\text{OH}$ radicals and using phosphate buffer as the solvent, which reacts with hydrated electrons in deaerated solution increasing the $\text{H}^{\cdot}$ atom yield ($k = 1.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$); (iii) finally, the quantitative radical generation can be estimated using the radiation chemical yield (G) in $\mu\text{mol J}^{-1}$ units.^{63,64} The use of radiations turned out to be very important in order to envisage novel pathways of amino acid degradation by desulfurization processes and to establish their relationship with the lipid isomerization.

In case of methionine, this amino acid was already individuated for its role in oxidative stress with the formation of the corresponding sulfoxides.^{65–68} Also irradiation conditions were described to produce methionine oxidation, thought to be induced by $\cdot\text{OH}$ radical attack. More recently, novel mechanistic pathways have been described under anaerobic and aerobic conditions,⁶⁹ which can cause desulfurization according to Scheme 5.

It can be seen that the attack of hydrogen atoms occurs mainly to S centers with the formation of a sulfuranyl type radical **1**, which undergoes a β -fragmentation with the ejection of the MeSH moiety and formation of a C-centered radical. The fate of these species under anaerobic conditions is to give α -amino butyric acid **2** and $\text{MeS}^{\cdot}$ radical; under aerobic conditions, the C-centered radical can be trapped by oxygen and the corresponding peroxy radical can fragment and generate homoserine **3** together with $\text{MeS}^{\cdot}$ radicals. In both cases, $\text{MeS}^{\cdot}$ species have a very high diffusibility and can induce lipid isomerization.

It is worth underlining that this desulfurization process leads to a chemical mutation of a naturally coded amino acid into not genetically coded amino acids. In particular, methionine also plays an important role in the protein synthesis being a methionine-containing triplet often at the start of this process. The consequences of this mutation have not yet been addressed. In this view, libraries of

Scheme 5 Transformation of methionine via sulfuranyl radicals **1** into α -amino butyric acid **2** and homoserine **3**.

desulfurated sequences can be useful references in proteomic analyses to identify the occurrence of such transformations in complex mixtures. A similar process can occur to CySH residues and can lead to the formation of alanine residues. This process was identified in the 60–70s under radiation conditions, but never combined with a tandem damage in the biological environment.^{70–73}

Details of the free radical mechanisms involving S-containing compounds are given in article **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**. The applications to a biomimetic model of tandem damage in liposomes will be described in the following sections.

2.3.2 Lipid Isomerization as a Tool for Individuating Protein Damage: the Tandem Protein–Lipid Damage

In case of peptide and protein structures, the radical attack can occur to various amino acids of the sequence. Proteomic analyses are useful for mapping the damages, and the individuation of sequence alterations at very low level of damage can suffer from low resolution. It turned out that lipid isomerization can function as a very sensitive detection system for the damage to S-containing residues. In fact, after formation of thiyl radicals by the mechanisms described in the previous section, the catalytic cycle of cis to trans conversion can start, involving an unsaturated fatty acid present in the medium.

The combination of desulfurization–isomerization represented an interesting hypothesis to be assayed by biomimetic chemistry, in order to propose a novel pathway of tandem damage by free radical stress. Unlike the standard double lesions that are produced by two separate attacks by radical species, the concept of a tandem lesion includes the occurrence of a first damage by a single attack that generates reactive species able to migrate and react with other molecules, producing a second damage. The tandem process can involve two different cell compartments, and a precedent example of this kind of damage was described in case of lipid and DNA molecules, which give rise to adducts thus connecting two apparently separated environments such as membranes and nucleus.⁷⁴

The model chosen for biomimetic chemistry was composed of a lipid substrate containing a cis double bond (i.e., phospholipids such as POPC) in the presence of a sulfur-containing amino acid, or a peptide/protein sequence, as shown in Figure 4.

In case of aqueous systems, lipids are hydrophobic molecules that spontaneously organize themselves in aggregates. The details of this organization will be treated in Section 3. To this system, a radical stress was applied and the reaction products were analyzed in order to check the occurrence of the cis–trans isomerization of the lipid partner together with the desulfurization of the amino acid counterpart.

The tandem desulfurization–isomerization process highlighted the occurrence of a reductive

Figure 4 Tandem protein-lipid damage by reductive stress to S-containing residues with formation of a diffusible thiyl radical which migrates into the lipid bilayer and causes the cis–trans isomerization.

radical stress, which is certainly less studied than the oxidative damage.^{75–78} Indeed, using ionizing radiations in aqueous systems, the formation of primary radicals from water occurs (Figure 3) and hydrogen atoms can be selected. These reactive species were already known for their specificity toward sulfur moieties,^{70–73} but the behavior examined in radiation chemistry was not extrapolated to a possible path in the biological environment. It is worth underlining that the occurrence of a reductive stress is still underestimated, although hydrogen atoms can be produced by reaction of dihydrogen phosphate anions with electrons ($k = 1.5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$).^{63,64} This process waits for more attention among the radical stress pathways.

Free radical conditions can affect sulfur-containing residues, either under anaerobic or aerobic conditions, and the result is the transformation of natural amino acids in other amino acids, which are natural but not genetically encoded. These transformations are quite different from those already evidenced under oxidative stress. In fact, methionine is known to be transformed into methionine sulfoxides (the two *R* and *S* sulfoxide epimers), and this is actually considered an antioxidant system also balanced by enzymatic redox complexes.⁷⁹

Novel mechanistic pathways were individuated using ionizing radiations, as described for the simple amino acids, and the fate of S-containing residues belongs to a scenario with different possibilities. Peptide and protein sequences were studied in this respect, such as amyloid β -peptide, bovine pancreatic RNase A, and human serum albumin,

among others. Amyloid β -peptide is an interesting substrate involved in the damage caused by radical stress to the nervous system, which induces formation of fibrils disturbing the neuronal membrane structure and functions.⁸⁰

Reductive radical stress was applied to the 40 amino acid sequence of the amyloid β -peptide and the transformation of Met residues into α -amino butyric acid occurred, as identified by high performance liquid chromatography (HPLC) separation and matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) analysis. The experiment was also carried out in the biomimetic model of liposomes to ascertain the occurrence of a tandem lipid damage induced by the reductive desulfurization of the peptide with the formation of a diffusible radical species ($\text{MeS}^\bullet$), which penetrates the liposome bilayer and induces trans lipid formation (Figure 4).⁸¹

In the case of RNase A and albumin, both disulfide bridges and Met residues were found to be involved in the damage and the corresponding lipid isomerization. The secondary and tertiary structures of the protein render some residues more exposed than others to the attack of free radicals and also the diffusibility of small reactive species such as hydrogen atoms plays a role in the amino acid involvement. For RNase A, a complete proteomic analysis was carried out, showing that desulfurization selectively affected Met79, Cys110, Cys58, and Cys72 during first stages of reaction.⁸²

In an overview of the sulfur-containing substrates involved in lipid isomerization, the reactivity of metallothioneins is intriguing, because these proteins are S-rich sequences containing methionine and also metal-thiolate clusters created by complexation of metals with CySH residues and inorganic sulfur (Figure 5). The effect of reductive conditions (H atoms and solvated electrons) on these sequences, containing zinc or cadmium as the metals, was examined together with the identification of a tandem lipid isomerization and the proteomic analysis.⁸³ In Figure 5, the possible S-centered radical generation from Met, CySH, and S-containing clusters is indicated.

Preliminary indications that Cd and Zn proteins behave differently have been obtained, highlighting the influence of the two different protein structures on the reactivity outcome. Coupling the radiation with the detection of the spectral changes by Raman spectroscopy, it was possible to envisage that

Figure 5 Pathways of free radical generation on Met, CySH, and S-metal clusters belonging to metallothioneins.

Cd-containing protein appears to respond with the S-metal cluster, whereas for Zn-metallothionein, the CyS-metal clusters is more reactive.⁸³ In both cases, liberation of $\text{HS}^\bullet/\text{S}^{\bullet-}$ species occurs (Figure 5). These diffusible species are effective lipid isomerizing agents, which are able to migrate in the lipid compartment and cause the trans isomer formation. This result adds other chemical information to the already known role of metallothionein as antioxidants⁸⁴ and suggests that the liberation of sulfur species could represent a signal in the biological environment, which triggers other responses and endogenous cellular defenses.

The reactivity of S-containing residues reinterpreted as a tandem process with lipid isomerization offers several hints for novel chemical pathways occurring in aqueous systems, thus expanding the scenario of the possible changes that occur under free radical stress.

3 LIPID ISOMERIZATION IN ORGANIZED SYSTEMS

Liposomes such as multilamellar vesicles (MLVs) and small or large unilamellar vesicles are widely accepted as models of membrane lipid assembly. In Figure 6, an example is shown with the phospholipid dioleoyl phosphatidyl choline (DOPC).

After an initial use of MLVs, the choice was oriented to large unilamellar vesicles obtained by the extrusion technique. These models are much closer to cell membranes, due to the presence of a single bilayer.⁸⁵ Depending on the polycarbonate filter size used for the extrusion, vesicles of circa 90-nm diameter can be prepared and form an almost transparent suspension, which is also suitable for studies under photolytic conditions.^{25,26} Aqueous and lipid phases are the two distinct compartments

Figure 6 Unilamellar vesicle or liposome formed by DOPC (dioleoyl phosphatidyl choline).

of this nonhomogeneous system; therefore, several characteristics should be taken into account for the reactivity toward free radicals. First of all, where is the location of the initiation step, that is, where does the formation of an initial radical species occur. When a vesicle system is used to model free radical processes, it is important to establish which method of radical generation to be used, because it influences the reactivity. For example, radical processes can be initiated by diazocompounds of general formula $\text{R}-\text{N}=\text{N}-\text{R}$, which are homolytically cleaved at the appropriate temperature thus giving $\text{R}^\bullet$ with the evolution of N_2 .⁸⁶ These azoinitiators can be either hydrophilic, the generation of radicals occurring in the aqueous compartment, or hydrophobic, generating radicals within the lipid compartment. On the other hand, if generation of radicals is obtained by irradiation, the radiation source is important. In fact, using continuous radiolysis (^{60}Co source) in aqueous

liposome suspensions, the initiation occurs by the water compartment due to the interaction of γ -rays with water that generates primary reactive species (Figure 3).⁶²

Another factor to take into account is the orientation given by the supramolecular arrangement of the lipid assembly, with the fatty acid chains of phospholipid molecules that form the hydrophobic core of the model membrane and the polar heads that face the aqueous internal and external phases. In liposomes, there is a precise arrangement of the hydrophobic core, which can influence the position of the double bonds in the bilayer and the subsequent radical reactivity. A similar effect was also shown for ionic processes in organized systems.⁸⁷ Therefore, the reactivity of the fatty acid double bonds to the radical attack in suspensions is not equal to solution. Finally, the distribution of substrates added to liposome system in the two compartments depends on their partition coefficient.

3.1 Supramolecular Organization and Positional Isomer Preference

Lipid organization is a very important factor for the reactivity. It must be underlined that the most feasible membrane model is represented by mono-lamellar vesicles that have a single lipid bilayer simulating the natural cell membrane. In the mono-lamellar system, the process of the lipid isomerization was studied, and for the first time, the regioselectivity of this process with a positional preference was shown. This was studied using an amphiphilic thiol, 2-mercaptoethanol, as well as with other thiols, such as H_2S ,⁸⁸ which are highly diffusible species, able to move without restriction from the aqueous phase to the lipid bilayer and vice versa.

The model of liposomes made of egg yolk lecithin contained different fatty acid residues, as shown in Figure 7, with a mean fatty acid composition of palmitic acid (C16:0) 32%, stearic acid (C18:0) 14.1%, oleic acid (9*cis*-C18:1) 27%, vaccenic acid (11*cis*-C18:1) 1.2%, linoleic acid (9*cis*,12*cis*-C18:2) 20%, AA (5*cis*,8*cis*,11*cis*,14*cis*-C20:4) 4.8%. Lecithin can simulate much closer the various types of fatty acids present in the natural membranes.

In the presence of thiols and free radical conditions, it was demonstrated that the double bonds

Figure 7 Composition of phosphatidyl choline (lecithin) from egg yolk.

Figure 8 Isomerization of the fatty acid residues in liposomes made of egg lecithin by diffusible thiol radicals. Normalizing the fatty acid content according to the double bonds, arachidonic acid (∇) is faster than linoleic acid (○) and oleic acid (●). The bar diagram indicates the different amounts of mono-trans isomers of linoleic acid found in liposomes at different irradiation times.

located closest to the membrane polar region are the most reactive toward the attack of diffusing radicals.^{28,89} In fact, linoleic acid residues in vesicles have the double bond in position 9 more reactive than that in position 12, and the mono-9-trans isomer was formed preferentially (Figure 8).

Looking at the composition of egg lecithin reported in Figure 7, the normalization of the fatty acid content according to double bonds showed that AA residues are the most reactive in vesicles compared to oleic and linoleic acids (Figure 8, bar diagram). This was due to the fact that the two double bonds in 5 and 8 are the first ones available to free radicals diffusing in the layer, therefore, the first to be isomerized by diffusible thiyl radicals.

Several information were obtained from this biomimetic study to be extrapolated to the lipid isomerization process occurring in a biological environment: (i) among different fatty acid residues, AA residues as very relevant markers of thiyl radical reactivity in membrane phospholipids. This fact can lead to the hypothesis that tissues with a high polyunsaturated content can be more exposed to the isomerization process. The vulnerability of tissues containing PUFA residues is well known in oxidative processes and described by the parameters of peroxidation index or oxidizability.^{90,91} Also in the case of isomerization, PUFA content can be evaluated and it is likely that different tissues can have an indicative isomerization index or isomerizability which could be calculated. (ii) The isomerization of PUFAs occurs by a step-by-step mechanism (as shown in Scheme 3); therefore, the first isomers to be formed are mono-trans isomers of AA. Actually, in the liposome models, it was suggested that the mono-5-trans and 8-trans isomers are the first isomers to be formed by an endogenous process by diffusible free radicals penetrating the bilayer, since these positions are the first encountered during diffusion. The isolation and characterization of the mono-trans isomers of AA was carried out, gathering data on the chromatographic conditions (thin layer chromatography and gas chromatography (GC)) and spectroscopic (nuclear magnetic resonance, NMR) measurements that allowed to distinguish the four mono-trans isomers (Figure 9).⁸⁹ (iii) considering the biochemical pathways of AA formation from linoleic acid (in Section 3.2), it turned out that the positions 5 and 8 are those most involved *in vivo* in the activity of the desaturase enzymes; therefore, they are significant to highlight

the occurrence of an endogenous isomerization with conversion of the natural cis isomers into trans. (iv) The experiments in liposomes suggested that lipid isomerization in natural membranes should lead mainly to mono-trans isomers, the second step (i.e., formation of di-trans isomers) being less probable at the low radical production expected *in vivo*. This is a very important indication for building the library of cis and trans lipid isomers in order to effect the recognition in biological samples. Moreover, the endogenously formed mono-trans isomers turned out to be distinguishable from the exogenous trans isomers derived from dietary contribution, as it is explained in Section 3.2.^{89,92–94} The extended library can involve other PUFA residues, such as the fatty acids of the ω -3 series (eicosapentaenoic acid and docosahexaenoic acid) and lipid substrates not only related to membranes. Attention should be given to geometrical isomers that are the only products of a free radical-catalyzed isomerization and it is particularly important to consider the regioselectivity of the isomerization process, which helps in individuating the double bond positions that can be involved.

Important factors examined in the liposome model were the partition coefficient of sulfur-containing compounds and the compartment of the radical initiation step, which have a role in the isomerization outcome. Hydrophilic, lipophilic, and amphiphilic compounds have a different behavior and the combination between the S-containing compound and the radical initiator can be a crucial step. In biomimetic models, a variety of biologically relevant sulfur-containing compounds, such as cysteine, glutathione, methionine, lipoic, and dihydro lipoic acids,²² were examined under different radical initiating conditions.

Radical initiation can be obtained in the aqueous compartment by several methodologies: (i) thermal decomposition of a hydrophilic azocompound, which can also simulate a biological situation, such as the repair reaction given by hydrogen-donation from cysteine and glutathione toward carbon-centered radicals; (ii) ionizing radiations, such as γ -irradiation of aqueous systems which gives e_{aq}^- , $HO^\bullet$, and $H^\bullet$ atoms as reactive species, and the possibility of selection of the reactive species under appropriate conditions (Figure 3)⁶²; direct photolysis that can mimic the irradiation effects of light.

Figure 9 Time course of the photolytical isomerization of methyl arachidonate by Ag-TLC and structures of some of the trans isomers.

By examining different combinations of thiols and initiators, it was established that hydrophilic compounds, such as cysteine, combined with a hydrophilic thermal initiator, did not give any isomerization of the lipid bilayer.²⁸ This behavior was easily explained by the fact that hydrophilic thiol radicals are not able to enter the lipid bilayer and therefore cannot reach the lipid double bonds. On the other hand, under γ -radiolysis conditions, lipid isomerization with cysteine occurred. The radical damage was found to be caused by hydrogen atoms ($H^\bullet$) able to attack the sulfur moiety of the amino acid, and produce a desulfurization reaction,^{76,82,95} as previously described in the tandem lipid–protein damage. It cannot be excluded that CySH residues in a different context would be able to interact with membrane lipids. In fact, these residues are also present in membrane proteins, such as the mitochondrial respiratory chain enzymes. However, by

comparing different thiols, it was evident that the more hydrophobic the thiol, the higher the ability of inducing the cis–trans lipid isomerization. It must be underlined that the evaluation of lipid isomerization in the membrane compartment does not exclude that isomerization could occur in other cellular compartments where lipids are present. In this case, it could be expected that regioselectivity changes; however, lipids are organized in any case, for example, in micelles, and the organization mode has to be properly addressed.

3.2 Lipidomics and Recognition of trans Lipids in Biological Samples

Transferring chemical and reactivity information to a biological context is the task of chemical biology. Lipid isomerization is an interesting process to

be connected with the occurrence of free radical stress in cells. In order to evaluate the impact of this process in cellular stress, two main issues have to be addressed: (i) the analytical protocols for the identification of cis and trans lipids and (ii) the biological significance of the geometrical isomerization.

Nowadays, the follow-up of the lipid transformations belongs to the field of lipidomics, a discipline that brought a renovation of the methodologies and biological interpretation of lipid structures and metabolism. Trends and opportunities opened by lipidomics have been discussed in different contexts.^{96,97}

Lipidomic follow-up of free radical stress includes several indicators: (i) polyunsaturated fatty acids, which are sensitive substrates to free radical conditions and are well known to be transformed or consumed by oxidative stress. Oxidation and degradation products of PUFA are stress biomarkers to be found as metabolites, together with the changes of PUFA content in comparison with normal conditions; (ii) trans isomers obtained by lipid isomerization, which have been recently introduced as biomarker of free radical stress. They can be important *per se*, as well as give an indirect information on other degradation processes, such as the desulfurization of S-containing substrates; (iii) the overall content of the different families of fatty acids (PUFA, monounsaturated, and saturated fatty acids), which can change under stress, which have several consequences for the organization of membrane compartment and its functioning.

These lipid indicators can be estimated by an analysis of all fatty acid types and isomers present in a tissue in comparison with known normal compositions. Owing to the enormous relevance of free radical processes for health, it is clear that lipidomic analyses and the identification of important fatty acid biomarkers can also help envisage protective and integrative strategies of intervention. In this way, lipidomics of free radical stress provides a beautiful example of a straightforward application of chemical knowledge to health and medicine, which is expected to develop in several directions in the future.⁹⁸

As mentioned in Section 1, trans fatty acids are subject of nutrition research, due to the fact that isomerization can occur during fat manipulation in food industries. Several papers appeared on the intake of trans isomers through the diet and

the correspondent detection of trans fatty acids in tissues.^{7,11,12,99–101} From these results, it is clear that trans isomers can be enzymatically processed *in vivo* and the unnatural trans geometry is incorporated in biological structures, thus, resulting in an alteration of the cis geometry of natural lipids. Up to now, it is not known whether the presence of trans isomers in eukaryotic cells can be detected and recognized by specific enzymes, which can remove this alteration *in vivo*. Certainly, their presence can produce a signaling activity at various levels; in particular, trans isomers can be sensed in membrane lipids influencing, for example, membrane properties, channel and protein functioning.^{102–105}

The hypothesis of trans fatty acids formed directly in tissues by an endogenous free radical process was formulated after the chemical studies in biomimetic models. Studies on *in vitro* and *in vivo* trans-free systems, such as cell cultures⁹⁴ and animals,^{106,107} gave information on the endogenous trans fatty acid formation. The first report described THP-1 cell lines (human leukemia cell line) analyzed for the membrane fatty acid content under different conditions. A basal content of trans lipids was found in controls (circa 2.7%, indicated as the relative percentage on the total fatty acid residues detected by GC) under normal incubation condition. The addition of the amphiphilic thiol 2-mercaptoethanol to the cultures caused a slight increase in trans isomers (circa 3.8%). On the other hand, glutathione was not able to induce a significant increase in trans isomers during normal incubation, indicating the different fate of thiols in cells. When these thiols are used under radical stress produced artificially in the cell cultures by γ -irradiation, trans lipid formation increased up to 15.5% of the total fatty acid content. According to the biomimetic chemistry assayed in liposomes, lipid isomerization can likely occur by diffusible thiyl radical species, either produced under normal metabolism or under radical stress, entering the membrane compartment from the aqueous phase and attacking the double bonds. Fatty acid analysis indicated that the most prominent residue in this transformation was AA, confirming the indications derived from liposome experiments. In fact, the supramolecular membrane organization renders the double bonds of different fatty acids nonequivalent, therefore, favoring the reactivity of AA and in particular the formation of mono-trans isomers of this fatty acid at positions 5 and 8.⁹⁴

Figure 10 Biosynthetic pathway from linoleic acid ($9cis,12cis\text{-}C18:2$) to arachidonic acid ($5cis,8cis,11cis,14cis\text{-}C20:4$).

As mentioned in Section 3.1, the reactivity of AA can be successfully applied to distinguish the trans isomer dietary contribution from the trans isomer formation by free radicals. Taking into account that ω -6 and ω -3 are essential fatty acids, in the former series, the intake of linoleic acid ($9cis,12cis\text{-}18:2$) provides the precursor for AA ($5cis,8cis,11cis,14cis\text{-}20:4$) (Figure 10). The two double bonds of linoleic acid taken from the diet can be cis or trans, depending on whether the ingestion of partially hydrogenated oils occurs. On the other hand, tracing the biosynthetic transformation of linoleic acid to AA, other two double bonds are formed by desaturase enzymes at positions 5 and 8 of AA, which can be only cis, unless subsequently modified endogenously by free radical attack.

The identification of the 5-mono-trans and 8-mono-trans isomers of AA started the library of trans lipid isomers,^{89,92,94} to be used as markers of endogenous isomerization in biological samples.^{91,93}

As far as analytical methodologies for recognition of trans lipids are concerned, the total trans content can be identified by infrared spectroscopy through the absorbance of the trans double bond at a wave number of 966 cm^{-1} .^{108,109} However, for a lipidomic study, the identification of each isomer is crucially important, GC being the most effective and sensitive methodology to apply under appropriate conditions. Optimal resolution can be achieved as reported in case of ω -6 and ω -3 derivatives.^{89,94,110} Figure 11 shows an example of GC runs of the fatty acid methyl esters obtained by processing egg lecithin, before (A) and after (B) the isomerization catalyzed by thiyl radicals. The good resolution of cis and trans isomers can be appreciated.

Mass spectrometry, even with soft techniques, are not yet so efficient for the specific geometrical isomer distinction. Indeed, up to now, small differences are reported, which cannot be useful for complex mixtures, consisting of intensity differences in the mass peaks in the fast atom

Figure 11 GC chromatograms of the cis and trans fatty acids found in egg lecithins (after transesterification of phospholipids): (A) before irradiation and (B) after irradiation in the presence of 2-mercaptoethanol. Fatty acid methyl esters: (1)-C16:0; (2)-C18:0; (3)-9-*trans*,C18:1; (4)-9-*cis*,C18:1; (5)-11-*cis*,C18:1; (6)-C18:2; (7)-C20:4. In the insets, the enlargements of the regions referred to trans isomers of linoleic acid (6a, 6b, and 6c) and arachidonic acid (7a, 7b, and 7c).

bomb mass spectrometry (FAB-MS) or chemical ionization mass spectrometry (CI-MS) spectra.¹¹¹ Trans isomers identification still rely on “classical” techniques, such as GC (coupled with flame ionization or mass spectrometry detection),¹⁰⁹ and on the “old” separation procedure by chromatography on silver nitrate-impregnated silica gel plates.¹¹² Lipids have to be extracted from the sample by known methodologies and then transformed into fatty acid methyl esters for the GC analysis.¹¹³

The detection of trans lipids have also been performed in humans, using blood as source of plasma or cell membranes. Obviously, other tissues can be used, but blood can be useful for routine analyses. Trans fatty acids have been detected in the plasma of smokers,¹¹⁴ in erythrocyte and lymphocyte membranes of children affected by atopic dermatitis⁹³ and in erythrocyte membrane phospholipids of centenarian offspring,^{91,115} in all cases being significantly different from healthy controls. It is remarkable that all these conditions can imply the increase in free radical stress and impaired defense.

4 FACTORS AFFECTING LIPID ISOMERIZATION

Biomimetic chemistry also allowed for a thorough examination of the factors that influence the cis–trans isomerization process of lipid double

bonds. The context of lipid isomerization can be correlated with the biological occurrence of an endogenous process; therefore, the models have to take into account the main factors present in a cellular environment: in particular, oxygen and free radical scavengers. Free radical reactivity can be studied in a competitive manner, taking into account the rate constant of each process and the relative concentrations of substrates at the reaction site. In this way, the evaluation of free radical reactivity leads to a predictable scenario, which is important to propose mechanistic views of biological processes. It is worth underlining that the chemical knowledge is the basis of the study on free radicals in biology and medicine.

4.1 The Role of Oxygen

The first factor to be considered in the biological environment is oxygen. The role of oxygen is very well known for PUFA causing the lipid peroxidation, a process that indeed occurs at the expense of fatty acids containing bisallylic positions. This field was first approached by chemists,^{1,116} which then motivated, and still it does, a huge amount of research in life sciences,¹¹⁷ as described in the articles **Lipid Peroxidation**. This topic can be certainly considered as a successful example of the fruitful relationship between chemical and biological investigations.

The steps that are interesting in the autooxidation process are the atom abstraction from the bisallylic position and the trapping by oxygen. Both steps can be involved in the protective action of thiol compounds. The peroxy radical can be quenched by H-donation from a thiol.¹¹⁸ It is also worth recalling that thiols react very fast with $\cdot\text{OH}$ radicals ($k = 1.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-163}$), therefore, quenching of initiation species can also occur. From all these reactions, thiyl radicals are generated, which can start the catalytic cycle of double bond isomerization with the rate constants described in Section 2.2. In the reactivity scenario, it should also be considered that thiyl radicals can add reversibly to oxygen (see **Radical-Based Damage of Sulfur-Containing Amino Acid Residues**) (Figure 12).

It is likely that the formation of thiyl radicals even from a biological repair in the presence of oxygen can be connected with lipid isomerization, whereas the presence of thiol may inhibit the occurrence of lipid peroxidation. The first model experiments showed that the $\text{HOCH}_2\text{CH}_2\text{S}^\cdot$ radical induced cis–trans isomerization of methyl oleate or methyl linoleate in *t*-BuOH solutions saturated with 10% oxygen (corresponding to 0.23 mM, which is more than that of a well-oxygenated tissue, i.e., $40 \mu\text{M}$ ¹¹⁹), without loss of PUFA as estimated by quantitative analysis.¹⁹

Figure 12 Initial steps of linoleic acid autooxidation and the intervention of thiol with formation of thiyl radicals.

It is worth mentioning that the study on oxidation of liposomes by hydroxyl and glutathyl radicals by γ -irradiation showed that degradation was prevented by adding the suspension with protein substrates. The competition with the multiple reactive sites present in the protein sequence was able to protect lipid oxidation initiated by thiyl radicals.¹²⁰ On the other hand, taking into account the protein desulfurization induced by radical damage described in Section 2.3.2, the scenario of thiyl radical formation and reactivity becomes more intriguing and worth further investigations in the model system of liposomes.

A recent competitive model of autooxidation/isomerization using micelles of linoleic acid, prepared by addition of a nonionic surfactant (TWEEN®-20) and 2-mercaptoethanol as the amphiphilic thiol, was assayed by ionizing radiation up to 400 Gy under various conditions. In air-equilibrated solutions, the cis–trans isomerization process was observed with a catalytic cycle of 370 together with a substantial amount of hydroperoxides. For the first time, peroxidation and isomerization processes supported by thiol compounds were compared, showing that the two processes can occur site by site and a 1:2 peroxidation:isomerization ratio was also estimated in the micelle model.¹²¹

4.2 Isomerization Inhibitors

As mentioned in Section 3.2, up to now there is no enzymatic system in eukaryotes able to recognize specifically trans fatty acids and process them, for example, by reconvert the cis double bond or eliminating the trans geometry. Evidently, alternative mechanisms provide protection to the cis double bond geometry of natural lipids. The molecular line of endogenous defense against free radicals comes from antioxidant vitamins and cofactors. Therefore, models were studied on the effectiveness of cis–trans isomerization in the presence of the most common antioxidants.²²

It should also be pointed out that the location of the antioxidants with respect to the various steps of the isomerization reaction is important. In fact, there is no doubt that the fatty acid double bond is located in a hydrophobic environment, especially considering the membrane bilayer compartment. On the other hand, if an initial generation of radicals

occurs in the aqueous compartment, hydrophilic antioxidants can also have a role in the quenching of isomerizing agents.

This different behavior suggests to perform experiments in homogeneous and heterogeneous systems in order to get a comprehensive scenario of the reactivity.

It is also important to assess the mechanism for the best inhibition of the lipid isomerization. For example, the RS[•] radical's ability to add to all-*trans* retinol ($1.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for GS[•]) and β -carotene ($2.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for HOCH₂CH₂S[•]) suggested that retinoid and carotenoid derivatives can be the best inhibitors of the cis–trans isomerization.^{122,123} Indeed, in *t*-BuOH solution of methyl oleate (0.15M), the isomerization catalyzed by the radiolytically generated HOCH₂CH₂S[•] radicals (75 mM 2-mercaptoethanol) showed an initial strong inhibition in the presence of 1 mM all-*trans* retinol acetate, the cis:trans isomeric ratio reaching the same equilibration point at a longer time.²² This lag time was due to the efficient scavenging of thiyl radicals from the conjugated diene until it is consumed.

The inhibition mechanism of α -tocopherol against thiyl radicals is based on the H-donation; this is a reversible process shifted to the right ($k_1 = 1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$; limit value of $k_{-1} < 10^5 \text{ M}^{-1} \text{ s}^{-1}$ for the reaction of cysteinyl radical with Trolox¹²³). This behavior renders vitamin E not very efficient in the inhibition of the isomerization of methyl oleate, in the above described conditions, which showed only a little delay in reaching the same cis:trans mixture without antioxidant.

On the other hand, the reaction of thiyl radicals with ascorbate anion occurs with a high efficiency (10^8 – $10^9 \text{ M}^{-1} \text{ s}^{-1}$) by electron transfer.^{22,119} Since ascorbate is present at micromolar levels in blood serum (50 μM ¹²⁴) and increases up to 10-fold levels in tissues,¹²⁵ it becomes the most natural sink of thiyl radicals in the body. Using ascorbic acid 6-*O*-palmitate, which is soluble in lipophilic environment, the efficiency of this compound was tested, finding the inhibition of the isomerization process by five to six times compared with the uninhibited reaction. It was quite easy to predict, and to demonstrate in liposome vesicles using the amphiphilic 2-mercaptoethanol, that the inhibition order is α -tocopherol $\ll$ ascorbic acid 6-*O*-palmitate $<$ all-*trans* retinol acetate. As previously mentioned, vitamin C radical anion also

acts in the aqueous phase by electron transfer with the isomerizing species.

Focusing on the importance of the cis geometrical integrity in eukaryotic cells, the role of different compounds and their synergies against lipid isomerization are expected to be further addressed, also expanding the application in medicine and health. The anti-isomerizing activity can parallel the well-known antioxidant activity, which is a very active field of research with the discovery of a huge amount of molecules having this inhibiting effect. However, caution must be taken in order to distinguish the effectiveness of a simple chemical inhibition from the activity in a biological system; therefore, models and protocols must be chosen appropriately.

4.3 Environmental Factors: Bacterial Isomerization

In living organisms, the membrane compartment is a central point of regulation through the so-called homeoviscous adaptation, which represents the ability of modulating membrane functioning and properties, such as permeability and “fluidity,” to the various environmental conditions, without changing consistently the final metabolic responses.¹²⁶ There are different mechanisms to effect the necessary modification, one of the most important relying on the phospholipids, in particular changing saturated/unsaturated ratio, as well as the chain length or branching of the fatty acid residues. One of the reasons is a physical characteristic, since saturated, cis, and trans-unsaturated phospholipids display very different values of phase transition temperatures (T_m), that is, the temperature at which the transition between gel and liquid crystal phases occurs. For example, in the case of phosphatidyl cholines (Figure 13), where the R¹ fatty acid substituent is fixed as C16:0, and the R² varies through the series C18:0, 9*trans*-C18:1 and 9*cis*-C18:1, T_m values are 41.5, 35, and -3°C , respectively.¹²⁷

Also, the molecular shapes of saturated and cis-unsaturated lipids are quite different, since the cis geometry confers a kink in the lipid hydrocarbon chain, with an angle of circa 30° in the acyl chain. It is interesting to note that the lipid isomerization corresponds to a “cancellation” of the bending,

R = C16:0

R¹ = C18:0, or 9*trans*-C18:1, or 9*cis*-C18:1

Figure 13 Phosphatidyl cholines with different fatty acids in position 2 of glycerol.

because *trans* isomers also have a straight molecular shape, more similar to that of saturated compounds (Figure 14).

The packing of a lipid assembly follows the order: saturated > *trans*-unsaturated > *cis*-unsaturated, whereas the gross membrane property of “fluidity,” as well as permeability, follows the inverted order, so that at a physiological temperature, the *cis*-unsaturated residue ensures the most “fluid” state to the lipid assembly.

Membranes are the most sensitive cellular site to a stress. The fastest adaptive response occurs in membranes and is affected through the variation of the fatty acid composition of membrane lipids. In particular, the degree of phospholipid saturation is well known in animals and plants: at low temperatures, adaptation is afforded by enrichment of polyunsaturated lipids, whereas at high temperatures, the saturated fatty acid residues play the most important role for keeping the right properties of the lipid assembly.^{128–130}

With this premise, it is surprising that the *cis* and *trans* lipid geometry makes part of the regulation and adaptation responses only for prokaryotes.^{131–133} As a matter of fact, *trans* fatty acids were detected

as phospholipid residues in membranes of bacteria, and they were not dependent on growth, so that they did not derive from the *de novo* synthesis. In fact, they were also present in nongrowing cells, when lipid biosynthesis is absent and the total saturated and unsaturated fatty acid content cannot vary. Extending the analyses to other bacteria, it was shown that in obligate aerobic and anaerobic bacteria, biosynthesis provides oleic or palmitoleic acid, respectively, but formation of *trans* double bonds was not related to biosynthetic routes. The *trans* formation increased proportionally to the chemical or environmental stress applied to the bacterial cultures. *Trans* isomers were only geometrical isomers, in particular 9*trans*-C16:1 was found in anaerobic bacteria, such as *Pseudomonas* and *Vibrio* strains, as determined by GC analyses. It is worth noting that microbiologists apply a protocol in order to check the structure of the *trans* isomers present in bacterial lipids and the double bond position along the hydrocarbon chain, by preparing the corresponding methylthio derivatives by dimethyl disulfide addition, which have typical GC/MS spectra.¹³⁴

By adding a monounsaturated fatty acid, such as 9*cis*-C18:1, that is not present in *Pseudomonas putida* P8, it was incorporated in the membrane and, under addition of toxic compounds, also converted to the corresponding *trans* isomer.¹³⁵ The total amount of monounsaturated fatty acid remained constant, but the *cis/trans* ratio changed according to the stress conditions. This was the proof of a biological path carried out by a specific enzyme, which worked without changing the position of the double bond, but only its geometry. The existence of a *cis*–*trans* isomerase (Cti) was first hypothesized and then proved by cloning the Cti gene from *Pseudomonas* strains, followed by purification and

Figure 14 The molecular shapes of saturated, *trans* and *cis* fatty acids.

characterization of the enzyme.¹³⁶ Cti also work under anoxic conditions as well as in the presence of chelating agents, but the activity was strongly inhibited by 1 mM catecholic antioxidants, such as α -tocopherol and nordihydroguaric acid.¹³⁷ Some hypotheses of the enzyme activity have been forwarded, but the mechanism is far from being fully understood. In a study on *Pseudomonas* sp. strain E-3, the similarity between Cti and LOX was hypothesized on the basis of the common inhibition given by antioxidants.¹³⁷ However, chelating agents, which instead do not affect the isomerization, also inhibit LOX. A second mechanistic hypothesis was then formulated, consisting of the hydration–dehydration mechanism, similar to the formation of 3-*trans*-enoyl-CoA from the corresponding *cis* isomer.¹³⁸ Another mechanism based on the analysis of the carbon isotope fractionation experiment of the *cis*–*trans* isomerization proposed that the enzyme forms with the unsaturated substrate a complex as an intermediate, which allows the rotation of the carbon–carbon double bond to occur.¹³⁹ The involvement of free radicals during the enzymatic isomerization process is still to be demonstrated. It is also worth underlining that the lipid isomerization highlights its role as an evolutionary symbol, as already mentioned in the Section 2.1, since it means survival and adaptation for prokaryotes, whereas it means damage and loss of natural structural feature for eukaryotic organisms.

5 CONCLUSIONS

In the past years, lipid isomerization has been the subject of research in an interdisciplinary manner:

- in biomimetic chemistry showing the importance of liposomes to study the *trans* fatty acid formation and all factors influencing the reactivity; these studies also addressed the synthesis of molecular libraries made of *trans* lipids useful to biological and medical studies as well the role of S-containing compounds under free radical conditions;
- in biology, for a thorough understanding of membrane lipid characteristics and properties and the fatty acid behavior, as well as of the reactivity of S-containing compounds either as repairing and damaging agents in free radical stress;
- in lipidomics, applying the knowledge gathered from the models for studying physiological and pathological conditions, where a free radical stress can be linked to a change in the membrane lipids asset and the geometrical configuration.

In all these fields, the lipid isomerization will continue to be studied in order to get a complete picture of the role of geometry in life sciences. Owing to the relationships with lipid oxidative processes, lipid isomerization is also expected to gain more and more consideration either in the field of biomarker discovery and in the applications to medicine and health, thus contributing to a better definition of the scenario of the free radical consequences in living systems.

ACKNOWLEDGMENTS

The authors wish to thank all collaborators from different disciplines that contributed to the application of the fatty acid isomerism in the various fields.

1 ANTIOXIDANTS

Antioxidants can be broadly defined as compounds capable of slowing the overall rate of hydrocarbon oxidation. Antioxidants comprise an incredibly vast and heterogeneous family of small organic and inorganic molecules, as well as macromolecules and enzymes. This topic can hardly be addressed as a whole without focusing on a specific process, substrate, or environment. Here, we will focus primarily on processes occurring in biological systems or in solutions of organic compounds, wherein antioxidants often operate by inhibiting the free-radical chain oxidation (autoxidation) of organic substrates by lowering the steady concentration of chain-carrying radicals. In biological systems, the most relevant substrates for autoxidation lipids, and most often polyunsaturated fatty acids are found either as triglycerides or cholesterol esters in cellular membranes or circulating lipoproteins. The autoxidation of lipids is a process exemplified by the rancidification of edible fats and which parallels the oxidative degradation of motor oils and polymers. The process can be generalized for a substrate R–H (i.e., lipid or hydrocarbon) as in Scheme 1. The reaction is initiated by a radical species which, regardless of origin (e.g., photochemical, mitochondrial) or structure, abstracts a H atom from the substrate to form an alkyl radical R[•]. This radical then reacts with O₂ at essentially diffusion-controlled rates to form a peroxy radical (ROO[•]) which can propagate the chain reaction

Lipid Peroxidation.

Antioxidants capable of directly impairing this radical chain reaction are divided into two groups depending on their mechanism of interference. *Preventive antioxidants* interfere with the initiation process; that is, they retard or stop the initial formation of radical species. Examples of such are the enzyme catalase, metal chelators such as ethylenediaminetetraacetic acid (EDTA), and UV filters such as 2-hydroxybenzophenone. *Chain-breaking antioxidants* slow down autoxidation by competing with the propagation reactions; that is, they react with peroxy radicals faster than the oxidizable substrate to form species that do not propagate the oxidation chain. Representative examples include vitamins E and C as well as plant-derived flavonoids. In addition to these direct antioxidants, compounds that do not themselves possess antioxidant activity in solution or in model systems (i.e., micelles, liposomes, etc.), but can stimulate and increase the efficacy of the endogenous antioxidant defenses in biological systems, are usually classified as *indirect antioxidants*.

In the interest of space and given the context of this article as part of a comprehensive ensemble dealing with the most important aspects of free radicals in chemistry and biology, we will focus on radical-trapping, chain-breaking antioxidants in the following sections, while the discussion on preventive as well as on indirect antioxidants

Scheme 1 Mechanisms by which antioxidants can directly interfere with the free-radical autoxidation (peroxidation) process.

will be limited to some of the most relevant examples.

1.1 Preventive Antioxidants

1.1.1 Small Molecules

The autoxidative degradation of hydrocarbons is often initiated by light, either through Norrish-type carbonyl photochemistry that results in alkyl (or acyl) radicals which subsequently react with O_2 to yield chain-propagating peroxy radicals, or through the direct photolysis of labile (hydro)peroxide $O-O$ bonds to yield chain-initiating alkoxy radicals. This is the case for organic materials ranging from plastics¹ to human skin.² Therefore, UV filters, such as endogenous melanin or zinc oxide and benzophenone derivatives, which are able to absorb ultraviolet radiation (chemical filters, e.g., benzophenone) or reflect it (physical filters, e.g., zinc oxide), are among the most important preventive antioxidants. UV filters have long been employed for the protection of polymeric materials³

and are routinely incorporated in the formulation of protective paints and coatings for a variety of materials exposed to both air and light, as well as in the formulation of pharmaceuticals and cosmetics for the protection of human skin.⁴

Hydrogen peroxide and organic hydroperoxides can also give rise to chain-initiating hydroxyl and/or alkoxy radicals through their reduction by low-valent transition-metal ions (e.g., Fe^{2+} , Cu^{1+}). The best known example is the Fenton reaction (1), which involves the formation of a hydroxyl radical via a dissociative electron transfer from $Fe(II)$ to H_2O_2 .

As such, transition-metal chelating agents are important preventive antioxidants, acting to remove such ions from solution or maintain them in a higher oxidation state. EDTA is an example of a powerful chelating agent for transition metals and has been widely employed as an antioxidant in the food and cosmetic industries. Diethylenetriaminepentaacetic acid (DTPA) and other polyaminopolycarboxylic acids share similar chelating and antioxidant properties.

Likewise, desferrioxamine, produced by *Streptomyces pilosus*, and other natural and synthetic hydroxamic acid-containing siderophores⁵ with high affinity for iron ions, have been used to treat iron-poisoning and hemochromatosis and to decrease oxidative stress associated with the accumulation of redox-active iron in blood and tissues.^{6,7} Phytic acid (inositol hexakisphosphate, **1**), a natural component of many fruits and vegetables, also has good iron-chelating ability, which is responsible for its antioxidant properties and has stimulated interest in its use as a health-promoting nutrient.⁸

Melatonin (**2**), a pineal hormone well known for its activity as a regulator of circadian rhythm, has been ascribed several biological properties

associated with its antioxidant activity. While it has been shown to possess no relevant chain-breaking antioxidant behavior, it is an effective inhibitor of transition-metal-initiated lipid peroxidation.⁹

In addition to possessing moderate chain-breaking antioxidant behavior, curcumin, the compound believed to be responsible for the medicinal activity of the spice cumin (*Curcuma longa*), has $\log K_f = 5.2$ and 5.1 for Cu^{2+} and Fe^{2+} ,¹⁰ respectively, which has prompted its study in the therapy of Alzheimer's disease. Similar affinity has been recorded for synthetic bis-tacrine anti-Alzheimer drugs.¹¹ Indeed, transition-metal chelation and the prevention of increased oxidative stress associated with Fenton-type chemistry are currently seen as part of the therapeutic strategy for neurological disorders.

Compounds capable of decomposing hydroperoxides and hydrogen peroxide to nonradical products, either stoichiometrically or catalytically, are among the most important preventive antioxidants. Organophosphines such as triphenylphosphine (Ph_3P) and organophosphites $((\text{RO})_3\text{P})$ react in a 1:1 stoichiometry with hydroperoxides to yield the corresponding alcohols and phosphine oxide ($\text{Ph}_3\text{P}=\text{O}$) or organophosphate $((\text{RO})_3\text{P}=\text{O})$, respectively. Both phosphines and phosphites also react with chain-carrying peroxy radicals; however, the product of the reaction is the corresponding alkoxy radical, which is able to initiate a new oxidation chain. Thus, phosphines and phosphites are preventive antioxidants, but do not act as chain-breaking antioxidants.¹² Aryl and alkyl sulfides react with 1 equiv of hydroperoxides to form the corresponding sulfoxide and with a second equivalent to form sulfones, yielding, respectively, 1 or 2 equiv of alcohol.¹² Similarly, disulfides, RSSR , react with hydroperoxides to form thiosulfates,

RS(O)SR , which can decompose to yield sulfenic acids RSOH : their chemistry will be discussed in Section 3.

Several Se(II) - and Te(II) -containing organic compounds have been found to catalytically decompose hydrogen peroxide and organic hydroperoxides to water or alcohols respectively, in the presence of a stoichiometric reducing agent, most commonly a thiol, thereby behaving similar to the glutathione peroxidase (GPx) system (see below).^{13,14} Diselenides and ditellurides normally have even better catalytic activity, and in some cases they have been suggested for medicinal applications.¹⁵ Although the mechanisms can be quite complex, they are often exemplified by Scheme 2.

1.1.2 Enzymes and Proteins

Serum proteins, such as transferrin and ceruloplasmin, transport iron and copper ions, respectively, such that they are not free to catalyze Fenton-type chemistry and induce oxidative damage to the cell. These are examples of the so-called metal-deactivating preventive antioxidants.¹⁶ It has been shown that protein glycation can reactivate metal ions (e.g., by reducing protein affinity), thereby modulating their antioxidant activity.¹⁷

GPxs are a superfamily of enzymes containing reduced Se(II) in their active site. Their primary role is the reduction of hydrogen peroxide and organic hydroperoxides to water and alcohols, respectively. To do so, they make use of the tripeptide glutathione (GSH, γ -glutamylcysteinyl glycine) as the stoichiometric reducing agent.¹⁸ The proposed catalytic cycle at is depicted in Scheme 3.

Scheme 2 Hydroperoxide decomposition by organochalcogen species.

Scheme 3 Catalytic cycle of glutathione peroxidase (GPx).

Catalase, an enzyme composed of four protein chains each bringing a protoporphyrin IX (PPIX)-ligated iron, catalyzes the decomposition of hydrogen peroxide to water and molecular oxygen (2). This reaction is known to occur through the intervention of a high-valent iron-oxo complex, called compound I, as exemplified in (3 and 4).¹⁹

Monofunctional heme peroxidases and catalase-peroxidases (KatGs) catalyze the same reaction via a different suggested mechanism; in addition, nonheme Mn-catalases also decompose H_2O_2 to H_2O and O_2 via the intervention of a Mn(III)/Mn(IV) redox couple.²⁰ Catalase and other monofunctional heme peroxidases can catalyze the reduction of hydrogen peroxide at the expense of small molecules such as alcohols, aldehydes, phenols, toxins, or other reducing agents. Thioredoxin peroxidases (TPxs) are a family of nonheme peroxidases, whose active site contains the reduced cysteine residue $-\text{SH}$. TPx reduces hydrogen peroxide using thioredoxin as the stoichiometric reductant.²¹

Superoxide dismutases (SODs) are the primary defense against the damage that can be caused by superoxide ($\text{O}_2^{\bullet-}$) and its reactive progeny, such as its conjugate acid, the hydroperoxyl radical. These enzymes catalyze the dismutation of $\text{O}_2^{\bullet-}$ to

hydrogen peroxide and molecular oxygen (5).

Different types of SOD, inducible and constitutive, found in different biological systems may differ also in the redox-active metal(s) in the catalytic site. For instance, constitutive Fe-SOD and inducible Mn-SOD are found in *Escherichia coli*, while Mn-SOD and Cu,Zn-SOD are found in mammals; in all cases, together with catalases, they strongly contribute to the antioxidant defense machinery, as demonstrated by comparison with knock-out animals.²²

NAD(P)H:quinoneoxidoreductase (NQO) catalyzes the flavin-mediated two-electron reduction of quinones to the corresponding hydroquinones, avoiding the intermediacy of semiquinone radicals (anions), which would react with molecular oxygen to form hydroperoxyl (superoxide). These important antioxidant enzymes act both as preventive antioxidants because they avoid the formation of superoxide and as indirect antioxidants since they increase the amount of chain-breaking hydroquinones, contributing to the cellular antioxidant pool.²³

1.2 Indirect Antioxidants

Indirect antioxidants can act in many ways, but all ultimately enhance the activity of the antioxidant defense machinery, thereby leading to a more effective elimination of reactive-oxygen species (ROS) by balancing their generation and decreasing oxidative stress.²⁴

1.2.1 Enzymes

Glutathione reductase (GR)²⁵ and thioredoxin reductase (TR)²⁶ are examples of indirect antioxidants as they use NAD(P)H to reduce cysteine disulfides in glutathione and thioredoxin, respectively, thereby increasing the pool of cellular antioxidants. Similarly, biliverdin reductase reduces biliverdin to the strong antioxidant bilirubin, and is therefore a major cytoprotectant.²⁷

Inducible heme-oxygenase-1 (HO-1) and constitutive heme-oxygenase-2 (HO-2) are expressed in several mammalian tissues and share the task

of converting pro-oxidant heme into biliverdin, which is subsequently reduced to bilirubin; therefore, both HO-1 and HO-2 can be regarded as indirect antioxidant enzymes.²⁸ Interestingly, HO-1, as well as NQO and other antioxidant enzymes, can be induced through so-called antioxidant responsive elements (AREs), which regulate gene transcription and antioxidant protein overexpression.²⁹

1.2.2 Small Molecules

AREs are sensitive to stimuli from redox-active xenobiotics; particularly quinones, but also hydroquinones and catechols. These compounds and many others (e.g., flavonoids), can act as both chain-breaking antioxidants (see Section 2) and indirect antioxidants as they increase the expression of antioxidant enzymes in the cell.

Isothiocyanates (ITCs) are the breakdown products formed by myrosinase hydrolysis of glucosinolates (GLs) contained in most Brassicaceae vegetables such as broccoli and cauliflower (Scheme 4). They have been attributed a multitude of health-promoting properties associated with their indirect antioxidant and detoxifying activity; indeed, many of them, most notably sulforaphane from *Brassica oleracea* var. *italica*, are potent inducers of antioxidant and phase II enzymes via stimulation of ARE.³⁰

2 CHEMISTRY OF PHENOLIC ANTIOXIDANTS

Phenols comprise the archetype of radical-trapping chain-breaking antioxidants. The antioxidant activity of phenols is the result of their rapid reaction with chain-carrying peroxy radicals, which far outpaces the rate at which peroxy radicals propagate hydrocarbon autoxidation. The general mechanism of the free-radical autoxidation of a substrate R-H

Scheme 5 Hydrocarbon autoxidation (6–9) and its inhibition by phenolic antioxidants (10 and 11).

and its inhibition by a phenol ArOH is given in Scheme 5.^{12,31,32}

As mentioned above, and elsewhere in this volume **Lipid Peroxidation**, hydrocarbon autoxidation is a free-radical chain reaction (Scheme 5). The process is initiated via one of the many ways already described, leading to the formation of an alkyl radical (6), which immediately reacts with molecular oxygen to form a peroxy radical (7). In the absence of a suitable inhibitor, the peroxy radical reacts with the oxidizable substrate (normally an unsaturated hydrocarbon) to generate the corresponding hydroperoxide (ROOH) and a new carbon-centered radical (8). The propagation sequence (7 and 8) competes with a number of termination events, most commonly the radical–radical self-quenching of peroxy radicals (9) to yield nonradical products. If propagation is faster than termination, the overall process becomes a chain reaction (autoxidation) and, following any initiation event, several propagation steps can take place before the chain reaction is terminated. The reaction in (7) is extremely fast and nearly diffusion-controlled (k_7 typically ranges from

Scheme 4 Formation of isothiocyanates from glucosinolates.

2×10^9 to $5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ in organic solvents at 300 K);³³ therefore the rate-determining step for chain propagation is given in (8) and the autoxidation of a substrate occurs efficiently when $k_p[\text{RH}] \gg 2k_t[\text{ROO}^*]_{\text{ss}}$, where $[\text{ROO}^*]_{\text{ss}}$ is the steady-state concentration of peroxy radicals. Since the rate of autoxidation depends on the ratio $k_p/(2k_t)^{1/2}$ (see below), this quantity is commonly referred to as the *oxidizability* of the substrate; some examples are given in Table 1 alongside their respective k_p and $2k_t$ values. It is clear from these values that the oxidizability of hydrocarbons can vary considerably, from very low values for unbranched saturated compounds to 1000-fold higher for polyunsaturated fatty acid esters and hydrocarbons.³³

Chain-breaking antioxidants, such as phenols, offer an alternative reaction pathway to propagation and termination, to inhibit or stop the autoxidation. They react with peroxy radicals (10) to yield a stabilized aryloxy radical (ArO^*) that is sufficiently unreactive toward the substrate RH to be unable to further propagate the oxidative chain. Indeed, in solution, phenoxyl radicals do not react with the oxidizable substrate at all; rather, they are sufficiently long-lived to “wait” for a second peroxy radical that is rapidly quenched (11) by adding to the aromatic ring to form a variety of peroxy-cyclohexadienones. For example, the reaction of 2,6-di-*tert*-butyl-4-methylphenol (BHT) with alkylperoxy radicals is illustrated in Scheme 6.

^bValues at 333 K.

^cThe value at 303 K is $k_p = 1.0$, Ref. 34.

Scheme 6 Reactions associated with the chain-breaking antioxidant activity of BHT.

Since reaction (11) is very fast for common phenolic antioxidants⁴² (e.g., $k_{11} = 4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for α -tocopheroxyl in chlorobenzene at 318 K⁴³), according to Scheme 5, each molecule of antioxidant quenches two peroxy radicals (i.e., it blocks two oxidative chains); therefore a phenolic antioxidant is said to have a *stoichiometric factor* of 2. Experimentally, the stoichiometric factor determined for the majority of monophenolic antioxidants in typical inhibited autoxidations at 303–323 K in organic solution is $n = 1.95 \pm 0.15$, which is in excellent agreement with the conventional value $n = 2$.

Despite its obvious relevance, the stoichiometric factor is not the most important parameter to consider in evaluating the performance of a chain-breaking antioxidant. In fact, it is the inhibition rate constant (k_{inh})—the rate constant for reaction (10)—that should be considered most important. Since inhibition competes with propagation, in order for a chain-breaking antioxidant to be effective, reaction (10) should be significantly faster than reaction (8), that is, $k_{\text{inh}}[\text{ArOH}] \gg k_{\text{p}}[\text{RH}]$. Phenolic antioxidants generally have k_{inh} values that fall into the range 10^4 – $10^6 \text{ M}^{-1} \text{ s}^{-1}$, with only very few exceptions. However, while the antioxidant activity of a given phenol will be directly proportional to its k_{inh} , its actual performance depends also on the substrate. For instance, BHT has a $k_{\text{inh}} = 1.1 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ in chlorobenzene at 303 K;^{37,44} in this solvent and temperature, it gives excellent protection of cumene ($k_{\text{p}} = 0.34 \text{ M}^{-1} \text{ s}^{-1}$) and quite good protection of tetrahydrofuran ($k_{\text{p}} = 4.4 \text{ M}^{-1} \text{ s}^{-1}$) but offers only very modest protection of styrene ($k_{\text{p}} = 41 \text{ M}^{-1} \text{ s}^{-1}$). With styrene, it is normally unable to completely stop the oxidation chain reaction, but it still competes with propagation, slowing down the oxidation of the substrate. For this reason, it might be more appropriate to describe it as a “retarder” of autoxidation in this context rather than an “inhibitor”, although such a description would have no actual chemical meaning. Indeed, any classification based on the antioxidant performance is valid only for a specific substrate and experimental setting (BHT is a retarder for styrene and an inhibitor for cumene) and should be avoided, as it might be misleading. On the other hand, it should be noted that the magnitude of k_{inh} is nearly independent of the oxidizable substrate; that is, it is very similar for different chain-carrying alkylperoxyl radicals,⁴⁴ with

the exception of very electron-poor species such as $\text{Cl}_3\text{COO}^\bullet$ which exhibit much higher reactivity.⁴⁵

2.1 Kinetic Methods

Quantitative measurements of the antioxidant activity of chain-breaking antioxidants, such as phenols, imply knowledge of their reaction kinetics with chain-carrying peroxy radicals. These measurements are normally performed in nonpolar organic solvents because of the good solubility of both the oxidizable substrates and most antioxidants, and also because they reproduce, to some extent, the apolar environment found in the lipid core of biomembranes and low-density lipoproteins (LDLs). Kinetic studies in water or aqueous environments provide complementary information; they often involve hydroperoxyl/superoxide radicals ($\text{HOO}^\bullet/\text{O}_2^{\bullet-}$). Beside these studies, a large body of scientific literature deals with the evaluation of the antioxidant activity, most often of natural compounds or crude natural extracts, by means of a number of rapid assays such as trolox equivalent antioxidant capacity (TEAC), oxygen radical absorbing capacity (ORAC), ferric reducing antioxidant power (FRAP), total radical-trapping antioxidant potential (TRAP), $\text{Cl}_3\text{COO}^\bullet$ assay, DPPH $^\bullet$ quenching assay, carotene-bleaching assay, crocin-bleaching assay, and several variations of these methods. All are based on a single fluorimetric or spectrophotometric reading, after a fixed time, to assess the development or disappearance of absorbance/fluorescence as a consequence of the reaction of the test compound with some radical species or oxidizing agent. In most cases, the radical species used in the assay are not physiological relevant species and have no relation with the actual autoxidation process. Often, results are expressed as the extent of quenching of the oxidizing species or as IC₅₀, which is the concentration of the “antioxidant” that will quench 50% of the oxidant after a fixed time. Therefore, in most cases these assays are different forms of *titration of the reducing ability* of the test compounds or extracts and afford no information on the kinetics of their radical-trapping chain-breaking antioxidant activity. While these measurements can be useful to make a rapid comparison of the antioxidant content of biological samples or extracts of unknown composition,

they should never be regarded as quantitative measurements of the antioxidant activity or be used to draw structure–activity relationships.

2.1.1 Inhibited Autoxidations

Inhibited autoxidation studies are arguably the best established among the quantitative approaches to evaluate the performance of chain-breaking antioxidants. They comprise determining the kinetics of the autoxidation of an appropriately oxidizable substrate under controlled conditions in the presence and absence of variable concentrations of an antioxidant. In order to control the kinetics of the autoxidation, the process is generally initiated by means of a compound that yields radicals at a known rate at a given temperature, so as to ensure a constant and well-defined rate of initiation (R_i , see (6)). The most common radical precursors are azo-alkanes, such as the lipid-soluble 2,2'-azobis(isobutyronitrile) (AIBN), which has a half-life $t_{1/2} = 2660$ hours at 303 K in benzene,⁴⁶ or 2,2'-azobis(2,4-dimethylvaleronitrile) (AMVN), which decomposes about 10 times faster ($t_{1/2} = 320$ hours at 303 K in toluene).⁴⁶ Water-soluble 2,2'-azobis(2-methyl-2-propanimidamide) (ABAP or AAPH) is often employed for studies in aqueous or hydroalcoholic solutions ($t_{1/2} = 330$ hours at 310 K in water, pH 7).⁴⁷ Other radical precursors such as peresters and peroxides are less common.

A general overview of radical initiators for lipid peroxidation has been provided by Niki.⁴⁸

The kinetics of inhibited autoxidation can be determined either by monitoring the disappearance of reactants—most commonly O_2 —or the formation of oxidation products—most commonly hydroperoxides. In the former experiment, the autoxidation is performed in a closed system and the consumption of oxygen is monitored during the reaction by one of several methods. The best established method is based on the use of a differential pressure transducer (Figure 1).^{44,49} Therein two identical reaction vessels placed in a thermostated bath are connected through low-dead-volume, inert teflon (PTFE) high performance liquid chromatography (HPLC) tubing to the opposite sides of a variable reluctance membrane of the differential pressure transducer and the equilibration/isolation of the two channels is allowed by a three-way valve. Both reaction vessels (reference and sample) are loaded with a mixture containing the oxidizable substrate (typically 1–4 M in concentration) and the initiator in a suitable solvent (typically chlorobenzene) having low vapor pressure at the temperature of the experiment (normally 30–50 °C). Solutions are continuously stirred to ensure equilibration with air inside the system. The antioxidant can be injected into the reaction vessels by means of a microsyringe through the opening of a glass tap. Following thermal equilibration, the two vessels are isolated, and any difference in pressure between the two channels is monitored as a function of time, after digitalization of the signal from the transducer.^{50,51}

Figure 1 Differential oxygen uptake apparatus for autoxidation kinetics.

Scheme 7 Relevant reactions in the uninhibited autoxidation of styrene.

The reactions occurring in the reference/sample flasks are described by (12)–(18) using styrene as an example of the oxidizable substrate (Scheme 7).

Unlike alkylarenes (e.g., cumene) and polyunsaturated fatty acids/esters (e.g., methyl linoleate), whose propagation proceed by H-atom abstraction by the chain-carrying peroxy radicals (as exemplified by (6)–(9)), styrene and other substrates which possess an activated C=C double (e.g., acrylic acid) propagate by addition of the peroxy radical to the double bond (14 and 16), thereby forming a styrene-dioxygen (or other monomer-dioxygen) copolymer in the autoxidation. Still, the kinetics of the autoxidation are identical to those of nonpolymerizable hydrocarbons and can be subjected to the same kinetic treatment.

Decomposition of the azo-initiator releases N_2 (12), after which the consumption of oxygen begins (13) to form the initial peroxy radicals. Following each initiation event, more O_2 is consumed during the propagation steps (13–16) until termination (17) occurs. Therefore, the pressure balance of the autoxidation depends on the number of propagation cycles occurring after each initiation event—commonly called the *chain length of autoxidation* by analogy with polymerization. Since the same reaction occurs in both the reference and sample chambers, the pressure difference that is recorded should be zero. However, in a typical experiment, a large

excess (1 mM) of a very good antioxidant (often α -tocopherol (α -TOH), $k_{\text{inh}} = 3.2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) is injected into the reference flask to completely stop autoxidation (except the initiation step). As a result, the pressure difference recorded between the two channels is due solely to the consumption of oxygen in the sample chamber, where it reflects the extent of propagation. Only the initial stages of autoxidation are monitored, under an excess of azo-initiator, in order to eliminate kinetic complications due to chain transfer reactions and self-initiation phenomena.³⁴ These oxygen consumption plots are therefore linear, as shown in Figure 2, plot A.

If the chain length is sufficiently large, the steady-state approximation can be applied for any transient species, $d[\text{R}^\bullet]/dt = d[\text{ROO}^\bullet]/dt = 0$, and it is possible to obtain the time evolution of the reactants (O_2 and RH) and products (ROOH) as follows:^{12,52,53}

$$\begin{aligned}
 \frac{-d[\text{O}_2]}{dt} &= \frac{-d[\text{RH}]}{dt} = \frac{d[\text{ROOH}]}{dt} \\
 &= \frac{k_p}{\sqrt{2k_t}} \sqrt{R_i} [\text{RH}]_0 + R_i \quad (19)
 \end{aligned}$$

In cases where the chain length is <30 , the last term can be neglected and the expression simplifies to

Figure 2 Typical oxygen consumption plots obtained during autoxidation of styrene (A) in the absence of and antioxidant, (B) in the presence of a very good antioxidant, (C) in the presence of an average antioxidant, or (D) in the presence of modest antioxidant.

$$\begin{aligned} \frac{-d[\text{O}_2]}{dt} &= \frac{-d[\text{RH}]}{dt} = \frac{d[\text{ROOH}]}{dt} \\ &= \frac{k_p}{\sqrt{2k_t}} \sqrt{R_i} [\text{RH}]_0 \end{aligned} \quad (20)$$

where $[\text{RH}]_0$ is the initial concentration of oxidizable substrate (since only the initial stages of autoxidation are monitored and actual substrate consumption is negligible), $k_p/(2k_t)^{1/2}$ is the oxidizability of the substrate, which has been previously introduced and has been measured for a variety of compounds.³⁵

If a small amount (1–50 μM) of antioxidant is added to the sample flask, inhibition (21 and 22) competes with propagation and the rate of oxygen consumption decreases, as shown in Figure 2.

A very effective antioxidant will produce an almost complete inhibition of oxygen consumption,

until the antioxidant itself is consumed because peroxy radicals are continuously formed by the initiator (plot B). Once the antioxidant has been completely consumed, the autoxidation proceeds at its uninhibited rate; that is, the rate of oxygen uptake is identical to that recorded without inhibitor. The length of the inhibited period τ provides the best experimental way to determine the stoichiometric factor n , as

$$n = \frac{\tau \times R_i}{[\text{ArOH}]_0} \quad (23)$$

where $[\text{ArOH}]_0$ is the initial concentration of the antioxidant. Alternatively, the same relation provides the simplest way to determine the rate of initiation R_i under the exact experimental settings used for the autoxidation. Thus, a parallel autoxidation is inhibited by a known amount of α -TOH, whose stoichiometric coefficient is 2, and R_i is obtained as

$$R_i = \frac{2\tau}{[\alpha\text{-TOH}]_0} \quad (24)$$

From the initial slope of oxygen uptake during the inhibited period, the inhibition rate constant k_{inh} can be determined according to (25).⁵² Often, the inhibited period is not so clearly identified (plot C) or the initial portion of the plot is not usable to measure the rate of oxygen consumption,

and therefore (25) can be conveniently replaced by its integrated form (26).⁵⁴

$$\frac{-d[\text{O}_2]}{dt} = \frac{k_p[\text{RH}]R_i}{2k_{\text{inh}}[\text{ArOH}]} + R_i \quad (25)$$

$$\Delta[\text{O}_2]_t = \frac{k_p[\text{RH}]R_i}{k_{\text{inh}}} \ln \left(1 - \frac{t}{\tau} \right) \quad (26)$$

It should be noted that (25) and (26) are obtained assuming that the autoxidation is not completely inhibited; that is, the process is still a radical chain reaction and obeys the associated kinetics; otherwise, the slope of the inhibited portion of the oxygen-uptake plots would merely reflect the reaction of the initiator with the antioxidant and the baseline drift of the instrument. Ideally, autoxidation experiments should be designed so that, during the inhibited period, a chain length of 6–12 is maintained, so as to minimize the contribution of k'_{inh} in the measured k_{inh} . This is normally done by adjusting the concentration of the antioxidant, or by selecting an appropriate oxidizable substrate. Indeed, our own experience with the three most common substrates, styrene, cumene, and methyl linoleate (which have largely different oxidizability, see Table 1), indicates that the difference in the measured k_{inh} for the same antioxidant is always less than a factor of two, and most commonly it is less than the experimental error ($\pm 20\%$). As such, the choice of substrate is dictated largely by experimental convenience.

In some cases, the efficiency of the antioxidant is so low that no clear inhibition period is observed and the oxygen consumption is only retarded (plot D). In such cases, k_{inh} can be determined using (27) as developed by Denisov and Khudyakov,⁵⁵ where R_{ox} and $R_{\text{ox},0}$ are the rates of oxygen consumption $-d[\text{O}_2]/dt$ measured in the presence (plot D) and in the absence (plot A) of the antioxidant, respectively, under identical experimental settings.

$$\frac{R_{\text{ox},0}}{R_{\text{ox}}} - \frac{R_{\text{ox}}}{R_{\text{ox},0}} = \frac{nk_{\text{inh}}[\text{ArOH}]_0}{\sqrt{R_i 2k_t}} \quad (27)$$

Alternative mathematical treatments have been developed by Darley-USmar *et al.*⁵⁶ and Roginsky *et al.*⁵⁷ Alternatively, the value of k_{inh} and the time course of changes in reactants/products can be obtained by computational methods, by simulating

the oxygen-uptake trace in accordance with (6)–(11) (or (12–18 and 21, 22)).^{58,59} It should be noted that the stoichiometric factor cannot be obtained from plots C and D, and it has to be assumed as 2 or determined using a substrate with a much lower k_p . It should be pointed out that, in plot C, although the rate of oxygen uptake changes during the autoxidation, the intersection of the linear regressions corresponding to the apparent inhibited and uninhibited portions of the autoxidation does not represent τ . In fact, since the rate of the apparent “uninhibited” portion of the autoxidation is still lower than that of the uninhibited autoxidation (under identical settings), the antioxidant has likely not yet been completely consumed, or an oxidation product may be inhibiting the autoxidation.

The kinetics of oxygen consumption during kinetically controlled autoxidations have also been studied using electron paramagnetic resonance (EPR) spectroscopy. Owing to the paramagnetism of O_2 , the line width in the EPR spectra of radicals obtained in oxygen-containing solutions is broadened by Heisenberg spin exchange. The experimental line width W can be described by (28), where W_{intr} is the intrinsic line width due to unresolved hyperfine splitting and relaxation phenomena and W_{ox} is the line broadening contribution due to oxygen. This depends on $r = 4.5 \times 10^{-8}$ cm,⁶⁰ which is the interaction radius between oxygen and the radical, the probability of spin exchange $p = 1$, and the sum of diffusion coefficients of oxygen (D_{ox}) and the radical (D_{rad}), according to (29).⁶¹ Once simplified to (30), the relationship between the experimental line width and the concentration of oxygen is clear. In practice, it is most convenient to use (31), which relates the oxygen concentration to the intensity I of the EPR spectral line (for a given concentration a radical species in solution).⁶²

$$W = W_{\text{intr}} + W_{\text{ox}} \quad (28)$$

$$W_{\text{ox}} = 4\pi rp(D_{\text{ox}} + D_{\text{rad}})[\text{O}_2] \quad (29)$$

$$W = W_{\text{intr}} + 4\pi rD_{\text{ox}}[\text{O}_2] \quad (30)$$

$$I^{-1/2} \propto W_{\text{intr}} + 4\pi rD_{\text{ox}}[\text{O}_2] \quad (31)$$

Hence, an autoxidation can be run directly inside an EPR sample tube in oxygen- or air-saturated organic or aqueous solution, in the presence of a sufficiently “inert” radical probe, which,

after appropriate calibration, will allow the direct monitoring of oxygen consumption from spectral changes in line width and/or intensity.⁶³ The method has been successfully applied to organic solvents using the persistent nitroxyl radical 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO)^{62–64} and in aqueous media, using coal-derived fusinite particles in suspension.^{62,63}

Another popular method to measure the rate of oxygen consumption during an autoxidation is based on its polarographic detection using a Clark-type microelectrode. This approach requires a platinum cathode polarized to approximately +0.8 V with respect to an anode of Ag[°]/AgCl, both immersed in the same KCl solution inside a glass chamber, and separated from a small (~0.6 ml) isolated sample chamber by a polyethylene septum that is porous to oxygen. As oxygen diffuses through the septum, an electrical signal is generated between the electrodes as a result of the reactions in Scheme 8.

This method is very sensitive, but suffers from limited reproducibility, which often allows only semiquantitative comparison of the kinetics of different antioxidants under identical experimental conditions. Furthermore, it is suitable only for water or aqueous mixtures, where unfortunately the majority of oxidizable substrates are insoluble. However, it has been particularly useful in studies of the autoxidations of lipids in aqueous heterogeneous mixtures, such as liposomes, or micelles (SDS, Triton X-100, etc.), chosen as representative biomimetic models.^{65,66}

Although quantitative kinetic measurements are possible in micelles or liposomes, the kinetic treatment is complicated by the partitioning of the substrate, the initiator, and the antioxidant between the aqueous and lipid phases.^{67,68} Furthermore, the values of k_{inh} measured in these biomimetic systems, for most antioxidants, are orders of magnitude lower than the actual value in a homogeneous solution,^{49,69} since they reflect the rate of exchange of peroxy radicals and/or the antioxidant between micelles or between “compartments”.^{68,70} Such a rate of

exchange, in turn, reflects both the lipophilicity of the reactants and the lifetime of the supramolecular aggregate.⁷¹

The formation of oxidation products in an inhibited autoxidation should, in principle, mirror the consumption of O₂, and can be treated kinetically at the same way. This approach has often been applied to autoxidations of biological samples (e.g., LDLs or tissue extracts), or in models of biological samples (e.g., micelles and liposomes), and therefore has rarely resulted in the actual determination of absolute k_{inh} values. Nonetheless, owing to their widespread use, some relevant examples of this approach will be briefly mentioned here.

Hydroperoxides originating from the autoxidation of organic substrates have traditionally been determined by iodometric analysis, based on titration with sodium thiosulfate of iodine released upon incubation of the oxidized sample with potassium iodide, according to (32):

Alternative spectrophotometric methods, based on colorimetric redox reactions, have also been proposed.^{72,73} Selective chemiluminescent assays⁷⁴ and enzymatic assays have also been applied to monitor lipid peroxidation in biological samples. A particularly popular method in this context is based on the glutathione oxidase-catalyzed oxidation of GSH to its corresponding disulphide (GSSG), for which hydroperoxides formed during lipid peroxidation can be used as the stoichiometric oxidant. The formation of GSSG can then be monitored via its reduction to GSH by glutathione reductase at the expense of NAD(P)H, which is monitored spectrophotometrically at 340 nm.

Alkyl hydroperoxides originating from autoxidation of saturated hydrocarbons have been sampled during the autoxidation, reduced to the corresponding alcohols with sodium borohydride or triphenylphosphine, and analyzed by gas chromatography (GC) or gas chromatography-mass spectrometry (GC-MS).^{75,76}

The primary products of polyunsaturated fatty acid (PUFA) autoxidation are conjugated diene hydroperoxides, which exhibit UV absorbance around 234 nm.⁷⁷ To avoid interference by other UV-absorbing species, the progress of the reaction

Scheme 8 Electrochemical reactions at the Clark-type electrode for oxygen detection.

can be monitored at regular time intervals by HPLC-UV analysis of the reaction mixture.^{78,79} Alternatively, HPLC analysis can be performed on samples after reduction of the conjugated diene hydroperoxides to the corresponding alcohols with triphenylphosphine.⁸⁰

Several methods have been developed to monitor the formation of a variety of markers of lipid peroxidation. Malondialdehyde (MDA), a decomposition product of oxidized PUFAs, has been monitored upon reaction with thiobarbituric acid to form a colored adduct with strong absorbance at 532 nm. Other oxidation by-products also give similar reaction and are collectively monitored as thiobarbituric acid reactive species (TBARS), either spectrophotometrically or by HPLC analysis. Indeed, a multitude of assays for the analysis of MDA and 4-hydroxyalkenals, using colorimetric or fluorimetric detection alone or coupled to HPLC, have been described over the years, and in some cases they have been implemented in commercial analytical kits.⁸¹

2.1.2 Peroxyl Radical Clocks

Peroxyl radical clocks offer a convenient approach to measure k_{inh} for most phenolic antioxidants. The basic principle of “radical clocks,” as devised by Griller and Ingold largely for the determination of kinetics of alkyl radical reactions,⁸² is based on the competition between a unimolecular reaction whose kinetics are known and a bimolecular reaction whose kinetics are to be determined (see **Radical Kinetics and Clocks**).

In the case of peroxyl radical kinetics, the clock, that is, the reference unimolecular reaction, was discovered by Porter's group by consideration of the reversibility of the reaction of highly stabilized alkyl radicals with molecular oxygen to yield isomeric peroxyl radicals.^{83–85} In bis-allylic radicals, such as those derived from PUFAs, the regioselectivity of oxygen addition depends strongly on whether the reactions are under kinetic or thermodynamic control. For instance, in oxidations of methyl linoleate (Scheme 9), oxygen partitions

Scheme 9 General mechanism for methyl linoleate (MeLin) oxidation under kinetic or thermodynamic control.

between the central position 11 (to yield peroxy **B**) and the terminal positions 9 or 13 to yield peroxy **C** and **D** with amounts of α and $1 - \alpha$, respectively. However, the initially formed peroxy **B** readily undergoes β -fragmentation to form the original alkyl radical, and this reaction, “the clock,” competes with H-atom transfer from the donor XH, for instance an antioxidant, to form the corresponding hydroperoxides **G**, **E**, and **F**.

Under chain reaction conditions, when the steady-state approximation can be applied to transient species, the ratio of the conjugated (**E** + **F**) to the nonconjugated (**G**) hydroperoxide products can be related to the rate constant for the first β -fragmentation, $k_{\beta I}$ and the rate constant for H transfer (k_{inh} if XH is the antioxidant) according to (33):

$$\text{MeLin}_{\text{fast}} \longrightarrow \frac{[\text{E} + \text{F}]}{[\text{G}]} = \frac{k_{\beta I}}{k_H[\text{XH}]} \left(\frac{1 - \alpha}{\alpha} \right) + \left(\frac{1 - \alpha}{\alpha} \right) \quad (33)$$

In the absence of a good H atom donor, isomerization of the peroxy **C** and **D** to the more stable *transoid* radicals **H** and **I** has time to occur, via a second β -fragmentation, and again oxygen will partition between the formation of the two *cis*, *trans* peroxy radicals or the two *trans*, *trans* peroxy radicals, which would either fragment back or react with the H donor to give the corresponding hydroperoxides **E** + **F**, as before, or **N** and **R** with *trans*, *trans* geometry. This second β -fragmentation ($k_{\beta II}$) provides a slower unimolecular process with which slower H-atom transfer reactions from less reactive XH can compete and their k_H be determined as detailed in (34):

$$\text{MeLin}_{\text{slow}} \longrightarrow \frac{[\text{E} + \text{F}]}{[\text{N} + \text{R}]} = \frac{k_H[\text{XH}]}{k_{\beta II}[1 - \beta]} + \frac{k_{\beta III}}{k_{\beta II}} \left(\frac{\beta}{1 - \beta} \right) \quad (34)$$

By analyzing the product ratios during methyl linoleate (MeLin) autoxidation in the absence or presence of variable amounts of reference antioxidant α -TOH in benzene at 37 °C, the authors determined $\alpha = 0.45$, $\beta = 0.69$, $k_{\beta I} = 2.6 \times 10^6 \text{ s}^{-1}$, $k_{\beta II} = 690 \text{ s}^{-1}$, and $k_{\beta III} = 50 \text{ s}^{-1}$, suggesting that the methyl linoleate “fast” clock, based upon $k_{\beta I}$,

and “slow” clock, based upon $k_{\beta II}$, are suited to determine k_{inh} for very effective antioxidants (e.g., α -TOH) and very modest inhibitors, respectively. Indeed, since both competing sets of products need to be accurately quantified in the reaction mixture in order to obtain reliable rate constants, it is an intrinsic limitation of the radical clock approach that $0.01 > k_{\beta}/k_H > 100$ (ideally $0.1 > k_{\beta}/k_H > 10$). Furthermore, reaction products need to be formed in relevant amounts to minimize analytical errors, which, in turn, requires that an oxidative chain reaction is maintained even in the presence of good antioxidants: a clear experimental shortcoming in some cases.

The kinetically controlled oxidation of allylbenzene (Scheme 10) offers a similar, albeit simpler, clock to time the reactivity of antioxidants, potentially covering the gap in reactivity of MeLin for most common antioxidants, with k_{inh} in the range 10^4 – $10^6 \text{ M}^{-1} \text{ s}^{-1}$. The kinetic competition shown in (Scheme 10, can be expressed as in (35), which links the ratio of the reaction products to $k_{\beta I}/k_H$: that is, it provides absolute values of $k_H = k_{inh}$ after calibration of the clock as

Scheme 10 General mechanism for allylbenzene (AB) oxidation under kinetic or thermodynamic control.

$k_{\beta I} = 2.6 \times 10^5 \text{ s}^{-1}$ and $\alpha = 0.74$ in benzene at 37°C . The main advantage of the AB clock is the ease with which reaction products can be accurately measured by GC.

$$\text{AB} \rightarrow \frac{[\text{T}]}{[\text{S}]} = \frac{k_{\beta I}}{k_{\text{H}}[\text{XH}]} \left(\frac{1-\alpha}{\alpha} \right) + \left(\frac{1-\alpha}{\alpha} \right) \quad (35)$$

In a more recent development, a versatile precursor of allylbenzyl radical **P** was identified as *tert*-butyl styrylperacetate (**3**), which promptly yields radical **P**, either by thermal or photolytic decomposition (36), in the presence of the antioxidant to be tested and in the desired solvent. This approach was determined with the following reference values (in benzene): $\alpha = 0.76$ and $k_{\beta I} = 1.7 \times 10^5$ or $1.4 \times 10^5 \text{ s}^{-1}$, depending on whether thermolysis or photolysis, respectively, is used to decompose the perester **3**.⁸⁶ The perester clock was calibrated in multiple solvents, and it requires only 5–10 mM concentrations of perester to set up the competition kinetics, making the determination of solvent effects on the peroxy radical trapping kinetics of assayed antioxidants possible using this methodology.

Overall, the MeLin and AB radical clocks have provided reliable k_{inh} values for a number of phenol-type antioxidants, often differing by less than a factor of two with respect to values determined by the inhibited autoxidation method. Hence they represent a valuable alternative approach for such measurements—especially for the determination of kinetic solvent effects, which may be investigated using **3**.

2.1.3 Direct Kinetic Measurements

Direct kinetic measurements of the reaction of antioxidants with peroxy radicals are important independent confirmations of k_{inh} values obtained from inhibited autoxidation studies, and provide the essential calibration data for other indirect methods, such as the peroxy radical clock measurements described above.

Laser flash photolysis (LFP) techniques (Figure 3a) would, in principle, be ideally suited to this task given the timescale of most phenol–peroxy radical reactions (microseconds) and the ease with which radicals are usually generated photochemically. However, this approach has been limited by some experimental obstacles. The most significant has been the lack of availability of convenient photochemical precursors to peroxy radicals, since pulsed lasers have fixed wavelengths (e.g., 355 nm for the third harmonic of the most common nanosecond-pulsed source, Nd:YAG) that may not be ideal for the photolysis of common radical precursors. For instance, aliphatic ketones have strong absorbance at around 180 nm ($\pi \rightarrow \pi^*$ transition; $\epsilon \sim 10\,000 \text{ cm}^2 \text{ mmol}^{-1}$), which is unusable for LFP, and a very weak absorbance at around 290 nm ($n \rightarrow \pi^*$ transition; $\epsilon \sim 15 \text{ cm}^2 \text{ mmol}^{-1}$), which is equally difficult to exploit since most antioxidants have higher absorbance at this wavelength. Azo-alkanes have band maxima at around 360 nm, but they are very weak, and radical generation proceeds with low quantum yields.

Another unfavorable feature is the weak UV absorbance of most alkylperoxy radicals.⁸⁷ Monitoring the decay of their UV absorbance is often impossible in a spectral region where all phenolic antioxidants, as well as the initiator, would absorb. This limitation can be overcome by monitoring the product radical, in the case that it has a distinct UV spectrum, or by using EPR spectroscopy to monitor the time evolution of the peroxy and/or the phenoxyl radical.

The reaction of α -TOH with cumylperoxy radicals was investigated in several solvents using a conventional flash photolysis apparatus as shown in Figure 3b, where photolysis was accomplished at 300–400 nm using the filtered flash from a Hg discharge tube. The lower efficiency of photolysis (compared to a laser) was compensated by the longer optical path for transient detection of 10 cm (as opposed to 0.7–1.0 in LFP instruments).

Figure 3 (a) Laser flash photolysis apparatus with UV detection of transient species; (b) conventional flash photolysis apparatus with UV detection of transient species; (c) second-order plot of k_{obs} obtained from pseudo-first-order fitting of the signal growth at 420 nm due to $\alpha\text{-TO}^\bullet$ radical (d), generated by reaction with cumylperoxyl radical in benzene at 298 K.

Scheme 11 Instantaneous and “clean” generation of cumylperoxyl radical by conventional flash photolysis at 300–400 nm of dicumylketone in benzene at 298 K.

The overall reaction (Scheme 11) was monitored by following the growth of α -tocopheroxyl radical at 420 nm (instead of the decay of the cumylperoxyl radicals) under pseudo-first-order conditions (excess of antioxidant), to obtain k_{obs} (Figure 3c) for each concentration of $\alpha\text{-TOH}$; these values, in turn,

yielded the second-order rate constant k_{inh} , according to (37), as $2.7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ in chlorobenzene and $3.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ in toluene at 298 K,⁸⁸ in excellent agreement with the value of $k_{\text{inh}} = 3.2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ measured in styrene/chlorobenzene (50 : 50) from autoxidation studies at 303 K.

Scheme 12 Generation of α -aminoalkylperoxyl radicals by LFP at 355 nm.

$$k_{\text{inh}} = k_{\text{obs}}[\text{ArOH}] + \text{intercept} \quad (37)$$

In (37), the intercept represents the reaction of peroxyl radical with the solvent and/or the initiator.

Lal     *et al.* have shown that α -aminoalkylperoxyl radicals, conveniently generated from the corresponding tertiary amine by LFP at 355 nm in the presence of di-*tert*-butyl peroxide (Scheme 12), have strong absorbance in the near-UV, from 350 to 450 nm. They were also able to show that these peroxyl radicals have reactivity similar to that of common alkylperoxyl radicals, and could therefore represent a convenient approach for LFP studies with phenols and other antioxidants.⁸⁹ For instance, the reaction of Et₂NCH(OO·)Me with α -TOH, BHT, and 4-methoxyphenol, monitored by following the decay of the peroxyl radicals at 380 nm, resulted in k_{inh} values at 296 K of 1.1×10^6 , 1.0×10^4 , and $6.1 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, which can be compared with the corresponding values obtained at 303 K with the inhibited autoxidation of styrene of 3.2×10^6 , 1.1×10^4 , and $1.0 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, respectively. Similarly, the α -aminoalkylperoxyl radical derived from tri(*iso*-butyl)amine, monitored at 390 nm, gave k_{inh} values with same phenols, which differed by less than a factor of two from the reference values (above), obtained in styrene autoxidations (at 303 K).

Pulsed radiolysis is a variation of LFP in which a pulse of electrons is used as the ionizing/initiating energy source. Peroxyl radicals (ROO·) and hydroperoxyl/superoxide (HOO·/O₂^{·-}) can be efficiently and instantaneously generated by pulse radiolysis in aqueous media, and monitored via their UV spectrum, to study the kinetics of their reactions with water-soluble antioxidants directly.

This powerful approach provides complementary information to LFP and autoxidation studies, which are mostly confined to organic solvents.

The primary limitation to this approach is that the radiolytic generation of peroxyl or superoxide radicals is never a clean process, and a number of both highly oxidizing and reducing species are formed simultaneously on essentially at the same timescale as the interesting peroxyl radicals. Therefore, kinetic studies often need to be corrected for the parallel (competing) reactions of these additional species, as exemplified in Scheme 13. Alkylperoxyl radicals are generated by subsequent reactions of unselective hydroxyl radicals with organic substrates in the aqueous solution and, depending on the selection of the organic substrate, this can result in a mixture of different alkyl radicals, and corresponding peroxyl radicals following their reaction with oxygen.

Despite these limitations, pulsed radiolysis has had broad applications in the study of antioxidants in water or aqueous mixtures, owing largely to the careful manipulation of reaction conditions in an attempt to control the yield of different species in solution.⁹⁰

For instance, the rate constant for the reaction of ascorbate in water containing 5% alcohol and/or of other organic solutes was determined as k_{inh} of $1.7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ with CH₃OO·; $2.5 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ with C₆H₅CH₂OO·; $4.7 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for HOCH₂OO·; and slightly higher with hydroperoxyl HOO·, the conjugate acid of superoxide, as $1.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, at 37 °C. The reactivity of a number of peroxyl radical species normally not accessible in autoxidation studies have also been investigated in water or water/cosolvent using

Scheme 13 Reactive species generated by γ -radiolysis of water saturated with O_2 , N_2O , and suitable organic solutes as the source of organic peroxy radicals.

pulsed radiolysis, such as $\text{Cl}_3\text{COO}^\bullet$ (and other halogenated alkylperoxy radicals), phenylperoxy radicals, pyridylperoxy radicals, and so on, demonstrating that these can be significantly more reactive than common alkylperoxy radicals.⁹¹

Time-resolved EPR detection of photolytically generated peroxy radicals overcomes the limitation due to their poor absorbance and high-energy UV transitions. Peroxy radicals normally give a broad singlet centered at $g \sim 2.016$, and are therefore observed at lower field with respect to the region where signals from phenoxyl radicals are found ($g = 2.0036\text{--}48$). Ingold and coworkers, by combining EPR spectroscopy and laser flash photolysis of di-*tert*-butylketone in the presence of oxygen and excess of phenolic antioxidant, have been able to measure directly their k_{inh} with *tert*-butylperoxy radicals, generated according to (38). Although results have probably been “contaminated” by the presence of some acylperoxy radicals, which are expected to be more reactive than alkylperoxy, the results of LFP–EPR measurements were in excellent agreement with k_{inh} values obtained using styrene autoxidation.⁴⁴

At lower temperature, the bimolecular decay of tertiary peroxy radicals becomes sufficiently slow

(e.g., $2k_t = 57 \pm 5 \text{ M}^{-1} \text{ s}^{-1}$ at 193 K for cumylperoxy radicals in propionitrile/cumene/*t*-BuOO*t*-Bu, 1:1:1)⁹² to be monitored directly with time-resolved EPR, using a UV lamp and a manual shutter for photolytic generation in the presence of the antioxidant to be investigated. Cumylperoxy radicals can be generated by continuous photolysis of di-*tert*-butyl peroxide in a propionitrile/cumene cosolvent mixture. This method, originally designed by Fukuzumi and coworkers,⁹³ allowed direct measurements of the kinetics of the reaction of cumylperoxy radical with a variety of phenols and other antioxidants in the temperature range 193–243 K (e.g., cf. Figure 4).^{92,93}

2.1.4 The Use of DPPH

The 2,2-diphenyl-1-picrylhydrazyl radical (DPPH $^\bullet$) is electronically related to alkylperoxy radicals (Scheme 14), but is sufficiently persistent to be stored in a bottle. Furthermore, it has a strong visible absorbance at 520 nm ($\epsilon = 1.3 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ in benzene) and a distinctive EPR spectrum ($\text{HSC}_{\text{N}2} = 7.94 \text{ G}$; $\text{HSC}_{\text{N}1} = 9.77 \text{ G}$; $g = 2.0036_4$ in benzene),⁹⁴ making it easy to monitor its reactions by visible absorption or EPR spectroscopy. For these reasons, it has largely been employed as a model radical species to study the formal H-atom transfer reactions of phenols and other antioxidants, assuming that its behavior reflects that of peroxy radicals.

Figure 4 Kinetic EPR measurement of the reactivity of 2,2,5,7,8-pentamethyl-6-chromanol (PMHC) with cumylperoxyl radicals at 193 K.⁹²

Scheme 14 DPPH radical, its polarized resonance form, and their similarity to alkylperoxyl radicals.

In fact, although the reactions of $\text{DPPH}^\bullet$ with phenols are several orders of magnitude slower, their kinetics in nonprotic solvents are found to reflect those of peroxy radicals.^{88,95} As such, for a series of phenols, the relative rate constants for quenching $\text{DPPH}^\bullet$ are expected to parallel those for quenching $\text{ROO}^\bullet$, allowing one to *estimate* the relative antioxidant activity. However, as we have noted above, only a full kinetic study in nonalcoholic solvents would provide meaningful indications, while single spectrophotometric determinations after a fixed time, or the so-called IC_{50} values (often determined in methanol or ethanol!), are of no value with regard to the antioxidant activity of test compounds.

2.2 Thermodynamic Methods

Since k_{inh} is the most important parameter in quantifying the antioxidant activity of phenols, major efforts have been devoted to understanding the factors that govern its magnitude. As the overall reaction of a phenol with a peroxy radical can be described as a formal H-atom transfer from the phenolic OH group to the peroxy radical, the thermodynamics of the reaction is reflected by the difference in the O–H bond dissociation enthalpy (BDE) of the phenolic O–H bond that is broken and the hydroperoxide O–H bond that is formed. Common alkyl hydroperoxides have similar O–H BDEs and, to clear up the field from

the large experimental errors associated with their measurement, Benson and Cohen recommend the general value of 88.6 ± 0.5 kcal mol⁻¹ for the ROO-H BDE, regardless of the nature of the alkyl substituent.⁹⁶ In order to be good antioxidants, it seems reasonable to expect that phenols should have significantly lower O-H BDEs than this value.

When $\log k_{\text{inh}}$ for a number of substituted phenols is plotted against their respective O-H BDEs in an Evans–Polanyi plot, a relationship as depicted in Figure 5 is obtained. The data points distribute linearly, but on three nearly parallel correlations representing from top to bottom, phenols without substituents ortho to the -OH group, phenols having methyl groups in the ortho positions, and phenols having *tert*-butyl substitution in the ortho positions, respectively. It is therefore clear that, to a first approximation, k_{inh} depends on two main factors: (i) the O-H BDE of the phenol and (ii) the steric hindrance around the reactive -OH group.

The empirical linear free-energy relationships in Figure 5 are: $\log(k_{\text{inh}}/\text{M}^{-1}\text{s}^{-1}) = X - (0.333 \pm 0.008)$ (BDE_{OH}/kcal mol⁻¹), where $X = 33.398$ for 2,6-H phenols; $X = 32.016$ for 2,6-Me₂ phenols; and $X = 30.080$ for 2,6-(*t*-Bu)₂ phenols.

Regarding steric hindrance, it should be noted that 2-*tert*-butyl-4-methoxyphenol, having only one ortho position occupied by the bulky *tert*-butyl (while the other is unhindered), is positioned in

the upper correlation (black square), that is, the same as where ortho unsubstituted phenols are found, indicating that both positions adjacent to the phenolic hydroxyl group need to be simultaneously hindered to affect the reactivity. Steric hindrance has a relevant role since, for instance, phenols having the same O-H BDEs, for example, 80 kcal mol⁻¹, would be ~100-fold or 2000-fold more reactive if they have methyls or no substituent in both ortho positions, respectively, in place of the bulky *tert*-butyls.

Despite the importance of steric hindrance, the O-H BDE remains the most important parameter in determining the reactivity of phenolic antioxidants and, as will be discussed later, largely depends on the electronic and stereoelectronic contribution of the ring substituents.

Among the many methods that might be used to determine the O-H BDEs of phenols, only a few have proven to be sufficiently accurate and reliable to provide useful insights. Indeed, it should be pointed out that an error as small as 4% in the determination of a phenolic O-H BDE corresponds to ~3 kcal mol⁻¹, which could lead to a predicted k_{inh} in error by over an order of magnitude at room temperature: that is, the difference between a good and a modest antioxidant! As a consequence, we will detail only a focused selection of such methods in the subsequent sections.

2.2.1 Radical Equilibration EPR

Radical equilibration EPR (REqEPR) is arguably the most accurate method for determining phenolic O-H BDEs, in particular for the determination of relative BDEs (i.e., BDE differences). The technique is based on the measurement of the equilibrium between two phenols and their corresponding phenoxyl radicals inside the cavity of an EPR spectrometer. One phenol serves as the reference compound whose O-H BDE has been determined to a high accuracy. The reference compound with respect to which all other BDEs have been determined is 2,4,6-tri-*tert*-butylphenol, whose O-H BDE was originally determined by Mahoney *et al.* using conventional calorimetry as 81.2 kcal mol⁻¹ at 298 K in benzene.⁹⁷ The BDEs of other phenols can then be determined by equilibration with this phenol, for example, galvinoxyl radical and 2,4,6-tri-*tert*-butylphenol (39):

Figure 5 Evan–Polanyi correlation between $\log k_{\text{inh}}$ (in chlorobenzene at 303 K) and BDE_{OH} (in benzene at 298 K) for common phenolic antioxidants having in the ortho positions no substituents ($\square$), two methyl groups (Δ), two *tert*-butyl groups ($\circ$), or one *tert*-butyl and no substituent in the other ortho position ($\blacksquare$).

In the case of persistent aryloxy radical species, such as the 2,4,6-*tert*-butylphenoxyl and galvinoxyl radicals, the equilibrium concentration of the two radical species can be easily obtained from the EPR spectrum of the two equilibrating radicals, while those of the corresponding diamagnetic species can be determined by difference, since the initial concentrations of the reactants are known.⁹⁸ However, experiments in the presence of rapidly decaying phenoxyl radicals require a more complex treatment, since the time evolution of each paramagnetic species needs to be quantitatively monitored, as illustrated in Scheme 15.⁹⁸

The approach was enormously simplified following the discovery that phenoxyl radicals react very rapidly with phenols,⁹⁹ such that the equilibrium between two phenols and their corresponding radicals is established before their spontaneous decay. Under “radical-buffer conditions”, that is,

Scheme 15 EPR equilibration of persistent with non-persistent radicals.

under continuous photolysis of the reaction mixture in the presence of a suitable initiator such as di-*tert*-butyl peroxide, by adjusting the intensity of irradiation and/or the amount of initiator, a steady concentration of equilibrating radicals is reached. The approach is depicted in Scheme 16.

The equilibrium constant is expressed by (40), where $[{}^r\text{ArOH}]_0$ and $[{}^u\text{ArOH}]_0$ represent, respectively, the initial concentrations of the reference and the unknown phenol, which is valid when the consumption of initial phenols during the experiment is negligible.

$$K_{\text{eq}} = \frac{[{}^u\text{ArOH}]_0 [{}^r\text{ArO}\cdot]}{[{}^r\text{ArOH}]_0 [{}^u\text{ArO}\cdot]} \quad (40)$$

The equilibrium concentrations of the radicals can be obtained directly from the EPR spectrum, which will be the sum of the individual spectra of the equilibrating radicals. When possible, the relative concentration of the two species is obtained by double integration for each species of a spectral region that is unblocked by the other. More conveniently and accurately, the experimental spectrum can be iteratively subjected to numerical fittings with computer-simulated spectra, until the correct relative amount of the two species is obtained, as illustrated in Figure 6.¹⁰⁰

From the measured value of K_{eq} , the Gibbs free energy change is obtained according to

Scheme 16 Reactions involved in REqEPR technique under “radical buffer” conditions.

Figure 6 Experimental X-band EPR spectra of $^{\bullet}\text{PhO}$ (a), $^{\bullet}\text{PhO}$ (b), and their mixture (c) obtained by photolyzing a mixture of the corresponding phenols in benzene containing 10% di-*tert*-butyl peroxide, and its computer simulation (D).

(41). Experimentally, the value of ΔS° associated with these equilibria is normally very small ($\pm 1 \text{ cal mol}^{-1} \text{ K}^{-1}$),⁹⁸ and therefore its contribution can be neglected (42) and the O–H BDE of the unknown species can be obtained according to (43).

$$\Delta G^{\circ} = \Delta H^{\circ} - T \Delta S^{\circ} = -RT \ln K_{\text{eq}} \quad (41)$$

$$\Delta H^{\circ} = \Delta \text{BDE}_{\text{OH}} = RT \ln K_{\text{eq}} \quad (42)$$

$$\text{BDE}_{\text{uPhOH}} = \text{BDE}_{\text{rPhOH}} + RT \ln K_{\text{eq}} \quad (43)$$

Because of the logarithmic relationship between the measured K_{eq} and ΔBDE , even rather large experimental errors result in very small errors in BDE_{OH} values, contributing to the accuracy of this approach. One distinctive feature of this approach is that all BDE values are somewhat interdependent, since each newly calibrated phenol can be used as reference for another calibration. In other words, values have all been obtained by consecutive equilibrations between phenols, and they all depend on the original reference value for 2,4,6-tri-*tert*-butylphenol. This implies that they are all internally coherent and, in case BDE value for the original reference is revised, they can all be corrected without any need to remeasure them. This happened in 2005, when the

O–H BDE of 2,4,6-tri-*tert*-butylphenol was revised to $80.1 \text{ kcal mol}^{-1}$.¹⁰¹ Therefore, and O–H BDE measured by REqEPR before 2005 must be revised downward by $1.1 \text{ kcal mol}^{-1}$.¹⁰¹

2.2.2 Photoacoustic Calorimetry

Photoacoustic calorimetry (PAC) is based on the measurement of a sound (acoustic) wave that propagates through a defined volume of solution as the consequence of a rapid enthalpy change associated with a photoinduced reaction.¹⁰² Only the heat released within a defined time interval (essentially instantaneous) can be detected by PAC through a piezoelectric sensor, while the gradual density changes associated with slow heat dissipation cannot be detected. For this reason, PAC has been applied to the measurements of enthalpy changes associated with very fast reactions initiated by a nanosecond laser pulse, and it has proven particularly suitable for the measurement of the O–H BDEs of phenols. The photoacoustic effect is a consequence of the thermal expansion associated with the deactivation (e.g., by internal conversion or chemical reaction) of an excited state produced by absorption of the energy of a photon $E_{h\nu}$. The fraction of absorbed

light f_{th} that is converted into thermal energy E_{th} is related to the absorbance A of the target compound according to (44):

$$E_{\text{th}} = f_{\text{th}} E_{\text{th}} (1 - 10^{-A}) \quad (44)$$

If the thermal expansion is sufficiently fast to be adiabatic, the thermal shock will translate quantitatively into an acoustic shock. Since the volume change is normally related to a number of factors, such as the heat capacity of the solution, the isobaric expansion coefficient, and the volume difference between products and reactants, PAC measurements need require extensive calibration before a reaction enthalpy can be obtained. Indeed f_{th} cannot be measured directly, and the photoacoustic response S_{obs} (the peak-to-peak amplitude of the first and main oscillation, expressed in millivolts) is used to determine the apparent fraction of light converted into heat f_{obs} by (45) (where c is an empirical response factor and χ_e is the adiabatic expansion coefficient of the medium), which in turn is needed to obtain the reaction enthalpy according to (46).

$$S_{\text{obs}} = cf_{\text{obs}} E_{\text{hv}} \chi_e (1 - 10^{-A}) \quad (45)$$

$$\Delta_r H^{\text{sol}} = \frac{\Delta_r V}{\chi_e} + \frac{(1 - f_{\text{obs}}) E_{\text{hv}}}{\Phi} \quad (46)$$

In this expression, $\Delta_r V$ is the change in volume associated with the reaction, while Φ is the quantum yield of the photoreaction; both need to be determined independently to obtain the heat of reaction.

The reaction commonly investigated to obtain BDE_{ArOH} values is described by (47), which is the sum of (48 and 49).

2.2.3 Computational Methods

Quantum chemical calculations represent an advantageous means to estimate the O–H BDEs of phenols and other antioxidants; in particular those that are sparingly soluble in organic solvents or that do not afford persistent radicals. Methods based on density functional theory (DFT) are arguably the most popular, because they provide good estimates of phenolic O–H BDEs at a relatively low computational cost.^{103–105} The accuracy achieved by these calculations is usually within $\pm 2 \text{ kcal mol}^{-1}$ with respect to experimental data. While these data may not be good enough to replace the best experimental measurements, it is certainly sufficient to give valuable insight into the behavior of most natural and synthetic antioxidants. Most importantly, they can predict the thermodynamic properties of molecules prior to their experimental study, representing an invaluable aid for their rational design. For instance, DFT methods have been successfully used to predict the O–H BDEs of new classes of antioxidants, such as pyrimidinols¹⁰⁶ and pyridinols,¹⁰⁷ and to rationalize the role of remote H bonding on the para-substituted phenols.¹⁰⁸

The absolute O–H BDEs of phenols in the gas phase can be obtained by calculating the enthalpy change for the reaction (50). However, to reduce inherent deficiencies in the computational methods at lower levels of theory, the isodesmic reaction (51) can be used to determine relative BDEs, which reveal the effect of substituents on the phenolic O–H BDE (ΔBDE). These can be combined with the “best” experimental O–H BDE of phenol to obtain a reasonable estimate of the absolute O–H BDE of the substituted phenol has recently been reported to be $86.7 \pm 0.7 \text{ kcal mol}^{-1}$ as the consensus value among carefully revised results from REqEPR, PAC, electrochemistry, and high-level computations.¹⁰¹ The isodesmic approach often yields calculated O–H BDEs that differ by less than 1 kcal mol^{-1} with respect to the best experimental results.

It should be pointed out that DFT methods do have some drawbacks. The contribution of strongly electron-donating (ED) and electron-withdrawing

(EW) substituents on the phenolic O–H BDE, calculated by using the popular B3LYP functional, have been found larger by about 1–2 kcal mol^{−1} than the experimental ones.¹⁰⁶ For instance, the Δ BDE of phenol substituted with *para*-OMe and –NO₂ groups have been calculated as –5.5 and +4.4 kcal mol^{−1}, respectively,¹⁰⁹ whereas the experimental values in benzene are –4.5 and +2.5 kcal mol^{−1}, respectively.¹⁰⁰ Furthermore, B3LYP has difficulties in reproducing results obtained with –CMe₃ substituents, so these are normally replaced by –Me for the purpose of calculations (considering that alkyl substituents bring very similar ED contribution into the phenolic ring). This approach, however, does not reproduce the effect of two *ortho*-CMe₃'s (i.e., disubstitution in 2,6) since the outcome depends on actual steric hindrance of the two substituents, as well as on their electronic contribution.

If the size of the investigated molecule is small, or if supercomputing facilities are available, more rigorous approaches are possible, such as the complete basis-set methods. Among them, the CBS-QB3 method has been shown to perform better than others in reproducing the absolute O–H BDE values (i.e., for (50)) and to describe the intramolecular H-bond effects on the O–H BDEs of phenols.¹¹⁰ The CBS-QB3 method has also been successfully employed to predict the O–H BDEs of nonphenolic antioxidants, such as sulfenic acids¹¹¹ and hydroxylamines.¹¹²

Unlike experimental measurements, computational methods allow the resolution of the effect of ring substituents on the strength of the phenolic O–H bond into the effect on the energies of the phenol and the phenoxyl radical derived therefrom, bringing a deeper comprehension of substituents' contribution to the properties and chemistry of phenolic antioxidants. The two effects are commonly termed *molecule stabilization enthalpy* (MSE) and *radical stabilization enthalpy* (RSE), whose difference yields the *total stabilization enthalpy* (TSE), corresponding to the Δ BDE with respect to phenol or a reference structure lacking the substituent under investigation, that is,¹¹³

$$\Delta\text{BDE} = \text{TSE} = \text{MSE} - \text{RSE} \quad (52)$$

2.2.4 Correlating Thermodynamic and Kinetic Data

The differences in reactivity among phenols with different substitution have been attributed to two main factors: steric hindrance and the phenolic O–H BDE. Both depend entirely on the identity and position of substituents on the aromatic ring. While the role of substituents on steric hindrance might be quite obvious, their contribution to the O–H BDE requires some discussion. In general, ED substituents lower the O–H BDE and increase the antioxidant activity, while the converse is observed for EW substituents; they decrease the reactivity toward peroxy radicals because they increase the O–H BDE. Figure 7 shows the dependence of O–H BDE^{114,115} (and k_{inh}) on Brown and Okamoto's para-substituent parameter σ^+_p for a series of 4-X-2,6-di-*tert*-butylphenols.¹¹⁶ The correlation is amazing, considering that σ^+_p have been defined by the kinetics of the solvolyses of substituted cumyl chlorides in aqueous acetone, while both the O–H BDE and k_{inh} determinations correspond to homolytic reactions in benzene (or chlorobenzene).

The effect of ring substituents also depends on their position: it is maximum for *ortho* and *para* positions relative to the –OH group, while it is modest in the *meta* position. The effect of ring substituents on the BDE_{OH} is approximately additive, and it is possible to use substituent Δ BDE values to calculate the BDE_{OH} of polysubstituted phenols for which experimental data are lacking (as an alternative to computational methods).¹¹⁷ However, additivity is adhered to only until the ring becomes “too electron rich” or “too electron poor”, that is, only in the case it contains, at most, one strong ED or EW group, while polysubstitution with alkyls is tolerated.

As mentioned, quantum chemical calculations allow the separation of the effect of substituents into two contributions: stabilization/destabilization of the phenoxyl radical and stabilization/destabilization of the parent phenol. The sum of the two contributions will result in their overall influence on the BDE_{OH}. Normally, ED substituents stabilize the phenoxyl radical and destabilize (or have little

Figure 7 Correlation between para substituent constant σ_p^+ (in water/acetone) and the BDE_{OH} (measured by REqEPR in benzene) for a series of 4-X-2,6-di-*tert*-butylphenols. Inset: Correlation between σ_p^+ and available $\log k_{inh}$ at 303 K in chlorobenzene.

influence on) the parent phenol (hence they decrease the BDE_{OH}); on the other hand, EW substituents normally stabilize the phenol, but have little influence on the phenoxyl radical (hence they increase the BDE_{OH}).

Some specific substituents require deeper discussion to understand their contribution; namely those having the general structure $-XR$, with X being an electronegative heteroatom with at least one lone pair or being a chalcogen atom (S, Se, Te).

When $-OR$ (or $-NR_2$) is in the para position, its contribution on BDE_{OH} and k_{inh} strongly depends on its stereoelectronics, that is, on its electronic properties associated with its conformation: the dihedral angle between the orbital carrying the lone pair and the ring π system. Comparison of compounds **19**, **45** (or **55**), and **56** (from Table 1) illustrates the concept. While they have the same pattern of substitution around the ring (any alkyl group has about the same ED character), 2,3,5,6-tetramethyl-4-methoxyphenol has a higher BDE_{OH} and much lower antioxidant activity than α -TOH or its analog 2,2,5,7,8-pentamethyl-6-chromanol (PMC). This is due to the geometrical constraint of the bicyclic system in tocopherols that forces the ring-O-C dihedral angle so as to have close-to-optimal overlap between the oxygen 2p-type lone pair and the ring π system. Both X-ray crystallographic studies of the phenol and EPR hyperfine splitting constants (hfs) measured for the phenoxyl radical in

solution, indicate an angle 17° between the oxygen lone pair and the axis of the ring π system in PMC. On the other hand, both X-ray and EPR find that the methoxy group in compound **19** is nearly perpendicular to the ring, as a result of the hindered rotation caused by the methyl groups in the 3- and 5-positions, with an angle of 89° between the oxygen lone pair and the axis of the ring π system, thereby preventing overlap (conjugation) between the *para*-oxygen and the ring. Indeed, compound **56**, where the aromatic ring is fused with a five-member ring containing oxygen, forces an ever better overlap of the oxygen lone pair with the ring π system (with an angle of 6°) accounting for its high reactivity (Scheme 17).⁴⁴

Since chalcogens tend to maintain a bonding angle much closer to the 90° of the atomic *p*-orbitals' geometry (as opposed to sp^3 hybridization of oxygen and carbon), as illustrated, introduction of -S- in place of $-CH_2-$ in the fused six-member ring in the analog **49** forces the geometry away from maximum overlap of the oxygen lone pair with the ring π system (the X-ray-measured and DFT-calculated angle is 30°), increasing the BDE_{OH} and decreasing the reactivity. Similarly, replacing the *para*-oxygen with sulfur or selenium in thiatocopherol (**53**) or selenotocopherol (**54**) has resulted in less effective antioxidants (as compared to α -TOH) because of the poorer conjugation of the chalcogen lone pair with the ring.

Table 2 BDE_{OH} values from REqEPR measurements in benzene at 298 K and k_{inh} values from inhibited autoxidation of styrene (or cumene) in chlorobenzene at 303 K for selected monophenolic antioxidants (n represents the stoichiometric factor; when not determined it was assumed as 2).

When –XR substituents with X = O, S, Se, or Te, are ortho to the –OH function, the effect due to the ED behavior is complicated by the occurrence of intermolecular H bonding with the “reactive” –OH, which increases the BDE_{OH} and decreases the antioxidant activity. Since such intramolecular H bonds have a strength on the order of ~3 kcal mol⁻¹, they significantly influence the reactivity of these compounds in apolar solvents.¹¹⁸ Organochalcogen substituents, besides participating intramolecular H bonding when they are ortho to the –OH,

have generally quite complex stereoelectronic properties, as they behave as EW groups in the phenol and as ED groups in the phenoxyl radical, upon rotation with respect to the ring skeleton. A detailed discussion on their stereoelectronic properties and effect on BDE_{OH} and reactivity has been provided.⁷⁹

Ortho disubstitution with very bulky groups such as *tert*-butyls produces a decrease in BDE_{OH} higher than that expected from their individual ED contribution. This may arise since they force the –C–O–H dihedral angle away from planarity, reducing the conjugation of the oxygen lone pairs with the ring and destabilizing the phenol.

2.3 Mechanistic Considerations

For over 60 years, much effort has been directed toward understanding the mechanism by which phenols inhibit hydrocarbon autoxidation.^{124,125} By the early 1960s, there was already consensus among most investigators that the reaction of phenols and chain-carrying peroxy radicals involved a straightforward abstraction of the phenolic H atom by a substrate-derived peroxy radical to give rise

Figure 8 Thermodynamic cycle representing the mechanistic possibilities for the formal H-atom transfer between a phenol and a peroxy radical.

to a hydroperoxide and corresponding unreactive phenoxyl radical.¹²⁶ While this reaction can be written as a formal H-atom transfer, two other possibilities can be envisioned: one wherein the proton and electron are transferred in distinct chemical steps, with the electron moving first and then the proton; or vice versa. These possibilities are demonstrated as a closed thermodynamic cycle in Figure 8.

2.3.1 H-Atom Transfer

Studies of the kinetics of the reactions of substituted phenols with peroxy radicals yield a clear linear free-energy relationship with Brown and Okamoto's σ^+ substituent constant that provide a negative reaction constant ρ^+ (Figure 7 and Refs 127 and 128), suggesting that partial positive charge is being formed in the reaction. This argues against rate-limiting proton transfer, and indicates that either H-atom transfer or rate-limiting electron transfer is the mechanism. Since both the aryloxy radical and the phenolic radical cation are electron-deficient, further delineation is difficult from this data alone.

Early work by Hammond and coworkers¹²⁹ revealed a very small or negligible deuterium kinetic isotope effect (DKIE) on the reaction, which led them to suggest that the mechanism was a rate-determining electron transfer followed by a rapid proton transfer. Shortly thereafter, Ingold and Howard¹³⁰ demonstrated that Hammond's experimental approach had been flawed (protium from product hydroperoxides in inhibited autoxidations could rapidly exchange with the deuterium in the deuterated phenol, precluding the observation of the DKIE), and demonstrated that there was indeed a sizeable DKIE in these reactions. For example, for

the reaction of BHT with cumylperoxy radical at 65 °C, the initial rate of oxidation was 4.2-fold lower in the presence of 1% D₂O than in the presence of 1% H₂O. The addition of an excess of D₂O to the oxidation mixture served to maintain BHT in its fully deuterated state well into the experiment. Representative DKIEs obtained for different phenols in the intervening years using the same approach is given in Table 3.

Since proton transfers are generally very fast processes, the consensus remains that this reaction goes by a H-atom transfer mechanism. This consensus is further supported by the fact that the kinetics are no faster in protic media, which would better support a proton-transfer/electron-transfer mechanism. Reaction medium can have a profound effect on both the kinetics and mechanism of the reactions of phenols with radicals—and in such a way that further supports the H-atom transfer mechanism. As discussed more thoroughly elsewhere in this encyclopedia, radical reactions in general and atom transfer reactions (see **Halogen and Chalcogen Transfer Chemistry**) in particular are generally not subject to significant differences in rate with changes in their environment. However, this observation is often made with respect to the polarity of the medium, rather than specific solvent–solute interactions. In fact, such specific interactions are key to the understanding of the kinetics of H-atom abstractions from phenols: H-bonding between the phenol and H-bond accepting solvents slow the kinetics down since they render the phenolic H atom unavailable for transfer to the radical—providing further support for a H-atom transfer mechanism. These kinetic solvent effects can be accounted for quantitatively via the expression in (55), which describes the predissociation model shown in Scheme 18.^{134,135}

$$k_{\text{H}}^{\text{S}} = \frac{k_{\text{H}}^{\text{O}}}{1 + K^{\text{S}}} \quad (55)$$

The equilibrium constant for an H-bonding interaction can be expressed as a function of the H-bond donating ability of the acidic partner and the H-bond accepting ability of the basic partner, given as Abraham's α_2^{H} and β_2^{H} constants, respectively. Using these in place of the equilibrium constant in (55) gives (56), which Ingold and coworkers have found quantitatively reflects the kinetics of most H-atom abstractions from phenols

Table 3 Representative deuterium kinetic isotope effects for the reactions of phenols and peroxy radicals.

by *tert*-butoxyl and diphenylpicrylhydrazyl radicals.¹³⁶ More recently, Pratt and Jha have shown that this also applies to the more relevant reaction of phenols with peroxy radicals.⁸⁶

$$\log k_H^S = \log k_H^0 - 8.3\alpha_2^H\beta_2^H \quad (56)$$

It is of interest to consider the foregoing in the context of the Arrhenius parameters that have been determined for these reactions. Although the data

are quite limited, Howard and coworkers determined the temperature dependence of the rate constants for the reactions of hindered (i.e., 2,6-di-*tert*-butylated) and nonhindered phenols with *tert*-butylperoxyl radicals in the early 1970s. They found that phenol reacted with $\log A = 7.2 \pm 0.5 \text{ M}^{-1} \text{ s}^{-1}$ and $E_a = 5.2 \pm 0.5 \text{ kcal mol}^{-1}$,¹³⁷ while hindered phenols have much lower $\log A$ values (e.g., for BHT, $\log A = 4.6 \pm 0.2 \text{ M}^{-1} \text{ s}^{-1}$ and $E_a \sim 0.8 \pm 0.2 \text{ kcal mol}^{-1}$).¹³¹ Reliable $\log A$ values are not

Scheme 18 Kinetic solvent effects on H-atom transfer from phenols.

available for 2,6-dimethylated phenols, the most commonly studied class, but they must be similar to phenol since reliable rate constants for similar compounds (e.g., **59**) have been measured up to $8.8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ (albeit with secondary peroxy radicals),¹⁰⁷ which would imply $\log A = 7.9$ when $E_a = 0$.

Let us consider the E_a values first. The difference between phenol and BHT can be accounted for simply by the difference in the strength of the O–H bonds that are broken in the reaction. While the O–H BDE of phenol is $\sim 87 \text{ kcal mol}^{-1}$, that in BHT is $\sim 81 \text{ kcal mol}^{-1}$ (see below). The BDE for **59** is even lower at $\sim 77 \text{ kcal mol}^{-1}$, suggesting an even smaller (negligible) barrier as suggested by the observed rate constant. Interestingly, the E_a determined for phenol is significantly lower than that determined for toluene under similar conditions ($E_a \sim 11 \text{ kcal mol}^{-1}$),¹²⁹ despite the fact that toluene and phenol have C–H and O–H BDEs that differ only by $\sim 2 \text{ kcal mol}^{-1}$ at most.¹¹³ This is an important point, as it underlies why the inhibition reaction of chain-carrying peroxy radicals with phenols can be so much faster than the chain-carrying reaction of peroxy radicals with hydrocarbons.

It has long been documented that H-atom transfer between two heteroatoms is much faster than H-atom transfer between carbon atoms, or carbon and heteroatoms.¹³⁸ This can be understood by the elegantly simple concept of triplet repulsion, advanced by Zavitsas,^{139,140} wherein the transition state for the formal H-atom transfer reaction can be envisioned as a H atom being exchanged between

two radicals of the same spin, represented by the configuration $X\uparrow H\downarrow Y\uparrow$ (see **Thermochemistry and Hydrogen Transfer Kinetics**). Since the spins on the X and Y fragments are the same, there is a repulsive energetic component associated with bringing them together. Since oxygen is more electronegative than carbon, the spin is more localized on oxygen than on carbon, which lowers the extent of triplet repulsion in H-atom transfer between phenols and peroxy radicals as compared to toluene and peroxy radicals. Zavitsas' view has been reinforced by theoretical calculations, which have attempted to separate out the contributions of the different electronic effects to the barriers of several degenerate H-atom transfers.¹⁴¹

Typical pre-exponential factors for H-atom transfer reactions are $\log A \sim 8 \pm 1 \text{ M}^{-1} \text{ s}^{-1}$,¹⁴² putting the reactions of phenols and peroxy radicals on the low end of things. Furthermore, there would appear to be a massive difference between the hindered and unhindered phenols. Previously, the low A-factors had been rationalized on the basis of the requisite formation of a H-bonded prereaction complex. However, it is unclear why the *t*-butylated phenol would then have a lower A-factor since the equilibrium constant for its formation of a H bond with a peroxy radical will undoubtedly be less than that for a nonhindered phenol. Furthermore, the $\log A$ value for the reaction of peroxy radicals with toluene is essentially the same as that for phenol,¹²⁹ while toluene is totally incapable of making a H bond. Needless to say, this still remains a bit of a mystery.

2.3.2 Computational Insights

The calculated transition state structures for the reactions of phenols and peroxy radicals suggest that they are more appropriately described as proton-coupled electron transfer (PCET) reactions.^{143–145} Formal H-atom transfer reactions can be characterized as taking place via a PCET mechanism when the proton and electron that make up the H atom are transferred between two different pairs of orbitals on the reacting partners.¹⁴⁶ This can be identified in the calculated transition state structures upon consideration of the relevant molecular orbitals (MOs), shown in Figure 9 for the reaction of phenol with a *tert*-butylperoxy

Figure 9 Lowest energy transition state structure calculated for the reaction of phenol with *tert*-butylperoxyl radical. [Reproduced from Ref. 145. © 2007, American Chemical Society.]

radical. The highest occupied molecular orbital (HOMO) (Figure 9e) shows that there is a bonding π interaction between one of the oxygen atom's 2p orbitals that contributes to the phenol's HOMO and one of the terminal oxygen atom's 2p orbitals that contribute to the peroxy's singly occupied molecular orbital (SOMO). In the SOMO (Figure 9f), this is an antibonding π interaction, but since there are two electrons in the bonding orbital and only one in the antibonding one, the π interaction is a net bonding. This O–O π interaction facilitates the electron transfer; in fact, the interaction implies that the unpaired electron is already delocalized across the π systems of the reacting partners in the transition state. At the same time, the proton is exchanged between the nominally nonbonding doubly occupied σ orbitals (i.e., lone pairs) on the same oxygen atoms. The syn orientation of the groups to which the oxygen atoms are bonded (i.e., Ph and *Ot*-Bu) is preferred over one that minimizes steric repulsion between them because of the positive orbital overlap between the two π systems (seen in the HOMO in Figure 9e), a secondary orbital interaction.

It is important to point out that the stationary point preceding the transition state structure on the reaction coordinate is one wherein the phenol is H-bonded to the peroxy radical. This preorients the reactants ideally for a PCET mechanism, while it makes attaining a transition state structure for a H-atom transfer (HAT) mechanism difficult, as it requires breaking the H bond in order to reorient the O–H group such that it is perpendicular to the plane of the aromatic ring and directed toward the peroxy radical such that the H atom is transferred between the two 2p orbitals of the oxygen atoms on the phenoxyl and peroxy radicals.

The intervention of a PCET mechanism is not inconsistent with the structure–activity relationships

described above. The introduction of ED ring substituents on the phenol raises the energy of its (π) HOMO, thereby enhancing the overlap with the (π^*) SOMO of the peroxy radical, facilitating the “ET” part of PCET.

2.3.3 Solvent Effects

In addition to slowing down the rate of reactions with chain-carrying radicals via sequestration of the phenolic H atom via interaction with H-bond accepting solvents, the reaction medium can also have a substantial effect on the mechanism of the formal HAT from a phenol to a peroxy radical. Two particular reaction conditions are most important to consider: the presence of added acid or added base.

The use of DPPH $\cdot$ as a model for peroxy radical reactions with phenols has lead to the conceptualization of the so-called sequential proton loss electron transfer (SPLET) mechanism, depicted in Scheme 19, which allowed rationalization of the unusually fast reactions of phenols observed in alcoholic solvents.^{95,147}

SPLET is essentially a proton transfer–electron transfer (PT–ET) mechanism with the difference being that the initial proton transfer (or proton loss (PL)) is from the phenol to the solvent (or a base),

Scheme 19 The so-called sequential proton loss electron transfer (SPLET) mechanism.

while the ET is from the electron-rich phenoxide anion to the electron-deficient DPPH[•], followed by fast proton exchange with the solvent (or the conjugated acid of the base). This mechanism, which affords very relevant accelerations in the formal H-atom transfer kinetics (by orders of magnitude in some cases), is suppressed by the addition of acids and can be seen as a form of base catalysis. Although it has been reasoned that SPLET would occur also with peroxy radicals,¹³⁶ this has yet to be demonstrated.¹⁴⁸

In recent work, one of us examined the inhibition kinetics of the α -TOH mimic PMC (compound **55** in Table 2) in the inhibited autoxidation of styrene in acetonitrile in the presence/absence of bases.¹⁴⁹ While the addition of 1 equiv of pyridine (PyrH⁺ has $pK_a = 12.3$ in MeCN) did not change the apparent value of k_{inh} measured for PMC ($pK_a \sim 25$ – 30 in MeCN), the addition of 1 equiv of 1,8-diazabicyclo[5,4]undec-7-ene (DBU), a much stronger base (DBUH⁺ has $pK_a = 24.3$ in MeCN), resulted in a significant drop in the antioxidant activity. In the presence of DBU, k_{inh} dropped by about one order of magnitude, and the apparent stoichiometric factor dropped from 2 to ~ 1 . Such an observation was attributed to the competing reaction of the phenoxide with molecular oxygen to yield superoxide (57 and 58), which can initiate a new oxidation chain or consume the antioxidant.

DPPH[•] has a positive standard reduction potential of about $E^\circ = +0.3$ V versus the standard calomel electrode (SCE) in organic solvents,¹⁵⁰ while the corresponding potentials for alkylperoxy radicals (lacking EW substituents) have been reported to range from $+0.3$ to $+0.7$ V versus SCE¹⁵¹ (e.g., for cumylperoxy $E^\circ = +0.65$ V versus SCE in MeCN⁹³). Therefore, both DPPH[•] and chain-carrying ROO[•] are strong one-electron oxidants, while phenoxide anions are normally good reductants with negative E° values¹⁵⁰ (e.g., $E_{red} = -0.52$ V vs SCE for α -TO[•]/ α -TO⁻ in MeCN¹⁵²), suggesting that ET from the phenoxide to both DPPH[•] or ROO[•] should be characterized by a $\Delta E^\circ \sim +1$ V and, therefore, be quite exergonic.

While studies assessing SPLET with DPPH[•] have all been conducted in carefully deoxygenated solutions, the presence of oxygen is unavoidable during autoxidations, as well as the conditions under which aerobic organisms subsist. Triplet oxygen is a weak one-electron oxidant, whose available E° value of ~ 0.5 V¹⁵⁰ suggests that the reaction in (58) should be essentially thermoneutral. Since the concentration of oxygen in nonaqueous media is $\sim 10^{-3}$ M, that is, about 1 million times higher than the steady-state concentration of peroxy radicals during an inhibited autoxidation (or even in greater excess in a cell membrane), the reaction of O₂ with the antioxidant-derived phenoxide anion is likely to outcompete the chain-carrying peroxy radicals. This suggests that, while the SPLET mechanism is possible with peroxy radicals, it appears to have no relevance under most model or biomimetic settings with monophenolic antioxidants.

Acids have recently been demonstrated to dramatically enhance the reactivity of phenols to peroxy radicals in organic solvents.⁹² The phenomenon was shown to be general for half a dozen common phenolic antioxidants and both organic and mineral acids. The rate acceleration increases with the concentration of acid, but not the acid strength; it is largest for carboxylic acids, and requires a relatively polar solvent such as acetonitrile to be effective. Acetic acid has been studied most thoroughly as a catalyst for this reaction and, as an example, has been found to increase the inhibition rate constant of pentamethylchromanol (determined by inhibited autoxidations of styrene) from 6.8×10^5 to 1.1×10^7 M⁻¹ s⁻¹ in acetonitrile containing 88 mM acetic acid. The acid-catalyzed reactions are characterized by an inverse deuterium kinetic isotope effect (e.g., 0.9 ± 0.3 for PMC) in place of the normal isotope effect that is observed in the absence of acid (e.g., 6.4 ± 1.3 for PMC). This key result, taken along with other mechanistic observations, suggests the mechanism in Scheme 20.

2.3.4 Fate of the Aryloxy Radical

Until now, we have not considered the fate of the aryloxy radical that is formed upon H-atom abstraction from the phenol. In fact, under most conditions, the phenoxyl radical goes on to rapidly react with another peroxy radical ($k = 10^8$ – 10^9 M⁻¹ s⁻¹).¹⁵³

Scheme 20 Proposed mechanism of the acid-catalyzed reaction of peroxy radicals with phenols.

This can sometimes lead to a complex mixture of products and, as such, this second chain-breaking reaction is often described to result simply in “non-radical products.” This is generally an appropriate description, as it underscores the observed stoichiometry of the inhibition of hydrocarbon autoxidation by phenolic compounds under ambient conditions; two chain-carrying peroxy radicals are consumed for each molecule of phenol (see below). The reaction of two peroxy radicals is comparatively slow (e.g., *t*-BuOO• dimerization occurs with $k \sim 10^3 \text{ M}^{-1} \text{ s}^{-1}$).¹⁵⁴

The combination of peroxy and phenoxyl radicals takes place to yield a dienone peroxide, the structure and fate of which depend on the substitution of the phenol. Taking an unsubstituted phenol as an example, the peroxy radical can add to any of the ring carbons of the phenoxyl that possess unpaired electron spin density (*ortho* or *para*). Following tautomerization to restore aromaticity, the weak O–O bond of the peroxide can then fragment and the resultant radical pair can undergo disproportionation to yield the corresponding quinone and alcohol (Scheme 21).¹⁵³

Phenoxyl radicals with substitution at both the *ortho* and *para* carbons still react with peroxy radicals very rapidly, but the lack of a geminate H atom precludes tautomerization, which means

that resultant peroxides decompose to generate more radicals in lieu of nonradical products. This is the reason why phenolic compounds generally have lower stoichiometric factors at higher temperatures. For example, while α -tocopheroxyl likely reacts with peroxy radicals to yield three primary peroxides as a result of coupling of the radicals at the *ortho* and *para* positions, at higher temperatures or over extended periods these peroxides give rise to six major products (Scheme 22),^{155–157} each of which requires the formation of intermediate alkoxy radicals that can go on to initiate chain reactions or consume additional antioxidant.

Therefore, at first glance it would appear that the lesser substituted phenols possess an advantage in their radical-trapping abilities—despite their lower reactivity—since they should more cleanly yield nonradical products. However, it is important to point out that, in competition with peroxy radical trapping by the phenoxyl, dimerization of phenoxyls can occur. For nonhindered phenoxyls, this reaction can be very fast (cf. Table 4) and can compete with capture of the peroxy radicals; for hindered phenoxyls, this reaction is insignificant with respect to reactions with peroxy radicals. The products of these reactions, namely (bis)dienones, may tautomerize to yield (bis)phenols if possible, which can undergo further reactions, some of which

Scheme 21 Representative peroxy radical trapping reaction for simple phenoxyls.

Scheme 22 Products derived from the second peroxy radical-trapping reaction of α -tocopherol, and their immediate precursor.

may not be as fast as those of the original compounds.¹⁵⁸

3 CHEMISTRY OF RELATED CHAIN-BREAKING ANTIOXIDANTS

3.1 Other Phenols

3.1.1 Catechols, Resorcinols, and Hydroquinones

The inclusion of a second hydroxyl group on the aromatic ring can dramatically alter the reactivity of phenols. The effect depends largely on the position where it is included; in general, catechols are slightly more reactive than hydroquinones, and both are much more reactive than resorcinols. The reason for the higher reactivities of catechols and hydroquinones versus resorcinols is based largely on thermodynamics. The O–H BDE in phenol is decreased by a significant margin upon introduction of the second –OH group in the *ortho* or *para* positions (e.g., comparing **60** ($79.3 \pm 0.3 \text{ kcal mol}^{-1}$) and **61** ($80.8 \pm 0.2 \text{ kcal mol}^{-1}$)),¹⁵⁹ but not when in the *meta* position; the O–H BDE of the analogous 3-methoxyphenol has been determined to be $86.7 \text{ kcal mol}^{-1}$.¹⁶⁰ The lower O–H BDE in catechols as compared to hydroquinones is the result of a strengthening in the intramolecular H bond as one of the H atoms is removed and the

semiquinone radical is formed. Consequently, catechols and hydroquinones have very large inhibition rate constants, for example, $2.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for **60** and $1.6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ for **61** in chlorobenzene at 30°C .⁵⁸ Resorcinols, on the other hand, are not documented to be very effective antioxidants.

The stoichiometry of the chain-breaking reactions is an important consideration in the antioxidant activity of catechols and hydroquinones. Catechols generally have $n = 2$, corresponding to the consequent abstraction of each of the labile phenolic H atoms by peroxy radicals and the corresponding formation of *o*-quinone as a product. In contrast, hydroquinones have stoichiometric factors that vary depending on the medium, ranging anywhere from 0.1 to 2. This is the result of the competing reaction of the intermediate *p*-semiquinone radical with O_2 .⁵⁸ This reaction, which has been shown to proceed with a rate constant of $2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at 298 K in chlorobenzene for the semiquinone radical derived from **61**, is believed

Table 4 Representative self-reaction rate constants for selected phenoxyl radicals. Data from Ref. 44.

ArO•	$2k$ (s^{-1})	ArO•	$2k$ (s^{-1})
	2.6×10^9		5.0×10^4
	1.0×10^9		8.6×10^3
	4.5×10^7		3.0×10^3
	2.0×10^5		0.1

to occur by a two-step addition/elimination mechanism, as is shown in (59). The hydroperoxyl radical can then carry on the autoxidation chain, negating the initial chain-breaking reaction of the parent hydroquinone with a peroxy radical. Depending on the partitioning of the *p*-semiquinone radicals between reactions with peroxy radicals and O_2 , stoichiometric factors between 0 (all reaction with O_2) and 2 (all reaction with $ROO\cdot$) can

be obtained. This is dependent on the O_2 concentration and steady-state $ROO\cdot$ concentration. The reaction is less important for catechols since the intramolecular H bond makes it more difficult to remove the H atom from the *o*-semiquinone radical.

There are many examples of biological catechols, resorcinols, and hydroquinones—in fact, many times these functionalities are found in the

same molecule! Perhaps the most famous hydroquinone is ubiquinol-10, also known as reduced coenzyme Q₁₀. It is an indispensable part of aerobic respiration, as it serves as a two-electron shuttle in complexes I and III of the mitochondrial electron transport chain. It is also an important antioxidant, possessing a (gas phase) O–H BDE of 78.5 kcal mol⁻¹¹⁶⁰ and reacting with peroxy radicals with a rate constant of $3.5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ in chlorobenzene.¹⁶¹ Despite having a similar O–H BDE, reduced coenzyme Q₁₀ is roughly one order of magnitude less reactive than α -TOH (see below), since the intramolecular H bonds between the reactive phenolic O–H bonds and the adjacent *o*-methoxy substitution in coenzyme Q₁₀ attenuate its reactivity. This was examined in particular detail for reactions of hydroquinones with alkoxyl radicals, where it was further demonstrated that, as a result of the intramolecular H-bonding interaction, the reduced coenzyme Q is not very susceptible to kinetic solvent effects, as are simpler phenols.¹⁶² These intramolecular H-bonding interactions also figure prominently in the thermodynamics of the reaction of coenzyme Q with radicals. Despite the fact that methoxy is a very good ED group (compare the O–H BDE of 86.2 kcal mol⁻¹ in phenol with the O–H BDE of 81.3 kcal mol⁻¹ in 4-methoxyphenol, determined by PAC¹⁶⁰), its presence in the *ortho* position does not yield a decrease in the O–H BDE because it is offset by the H-bonding interaction, which stabilizes the phenol with respect to the phenoxyl radical (O–H BDE of 86.6 kcal mol⁻¹ in 2-methoxyphenol by PAC¹⁶⁰).

The catechol moiety is found in countless plant-derived compounds, in particular, the phenolic acids (e.g., caffeic acid), or flavonoids such as flavonols and flavan-3-ols, examples of which are quercetin and epicatechin, respectively. While they display good antioxidant activities *in vitro* (e.g., quercetin and epicatechin have $k_{\text{inh}} = 4.3 \times 10^5$ and $4.2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, respectively, in chlorobenzene at 50 °C,¹⁶³ it is unclear whether this is of any significance *in vivo*. In fact, only a fraction (1–5%) of the amount contained in a fruit-rich meal is found in human plasma following ingestion and reaches only submicromolar levels.¹⁶⁴ The majority is metabolized by intestinal bacteria to yield the simpler phenolic acids (which do, however, retain the catechol moiety).

The most famous resorcinol could be resveratrol, found in relatively high levels in red wine. While it is a resorcinol, it is also a “simple” phenol on the other phenyl ring of the *trans*-stilbene. Since the vinyl substituent in the para position of the monosubstituted phenol can serve to delocalize the unpaired electron spin in the incipient phenoxyl radical, it is this moiety that actually reacts with peroxy radicals (its O–H BDE has been estimated to be 83.7 kcal mol⁻¹), and with a fairly good rate constant of $k = 2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ at 30 °C in chlorobenzene.⁵⁹ The resorcinol moiety is less reactive since the –OH groups are oriented meta to both the vinyl substituent and themselves, precluding delocalization.

3.1.2 Pyridinols and Pyrimidinols

For decades now, academic and industrial researchers alike have worked to improve the radical-trapping antioxidant activity of phenols. Most efforts to date have met with little success. This is simply because attempts to weaken the O–H bond further than that found in the most reactive phenols (i.e., $\sim 77 \text{ kcal mol}^{-1}$ in α -TOH) via introduction of more strongly ED substituent groups on the phenolic ring has lead to compounds that react directly with O_2 (e.g., **62**),⁴⁴ rendering them pro-oxidants rather than antioxidants. This is a consequence of the fact that both the undesired electron transfer chemistry and the desired H-atom transfer chemistry are functions of the energy of the HOMO, which goes up with increasing numbers and/or strengths of ED groups on the phenolic ring. Furthermore, the ED groups stabilize the radical cation derived from the one-electron transfer chemistry more so than the radical derived from

the H-atom transfer chemistry, making the electron transfer chemistry relatively more favorable upon ring substitution.

In the early 2000s, we presented a strategy to partially circumvent this problem, through the incorporation of nitrogen atoms in the phenolic ring.¹⁰⁶ The resulting compounds, 3-pyridinols and 5-pyrimidinols, containing one and two nitrogens, respectively, can be substituted with more ED groups since they start off more electron-poor than phenol itself.^{64,106,107,165} The nitrogen atoms are placed in the 3 and/or 5 positions since they are unable to yield the pyridone and pyrimidone tautomers that predominate when nitrogen is

incorporated in the 2 and/or 4 positions. While 3-pyridinols and 5-pyrimidinols have O–H BDEs that are ~ 1 and $2.5 \text{ kcal mol}^{-1}$ higher than in phenol, respectively, they can be weakened predictably upon ring substitution—as is the case for phenols. In doing so, air-stable 3-pyridinols and 5-pyrimidinols bearing strongly ED amino groups are readily synthesized, isolated, and purified, and are found to react with peroxy radicals up to two orders of magnitude faster than phenols (see Table 5 for some examples). The equivalently substituted phenols are essentially impossible to handle outside an inert atmosphere. Mechanistic studies support a H-atom transfer mechanism as for phenols ($k_{\text{H}}/k_{\text{D}} \sim 3$),^{64,106} a negative reaction constant for Hammett-type correlation with σ^+ ,^{107,165} HBA solvents slow kinetics,^{64,106,166} and theoretical calculations yield transition states consistent with a role for PCET in this process.⁹²

This development has prompted the study of lipid-soluble analogs of pyridinol **65** (which has the best balance of reactivity to peroxy radicals and stability in air, and most closely resembles α -TOH) under more physiologically relevant conditions, for

inhibit these processes in biological contexts is of great interest.

3.2 Aromatic Amines and Other Nitrogen-Containing Compounds

3.2.1 Aromatic Amines

Secondary aromatic amines have long been known to be effective inhibitors of hydrocarbon autoxidation, especially at high temperatures. The most commonly encountered amines are substituted diphenylamines (**67**), so we will consider their reactivity in detail here. However, it should be noted that many other diarylamines are, or have been, used industrially including *N*-phenyl- α -naphthylamines (**68**) and *N*-phenyl- β -naphthylamines (**69**) as well as *N,N'*-diphenyl phenylenediamines (**70**), and still other aromatic amines have been suggested as antioxidants (such as phenothiazines **71** and phenoxazines **72**), but are unlikely to find widespread use because of their instability in air.

example, in human LDL,^{167,168} and unilamellar vesicles (liposomes) comprised of polyunsaturated lipids.⁸⁰ Since the peroxidation of membrane lipids has been implicated in virtually all degenerative diseases, the potential for these compounds to

The initial step of radical-trapping chain-breaking activity is little different from that of phenols. The key step is a formal H-atom transfer from the diphenylamine to a peroxy radical, which yields a diphenylaminyl radical (**60**).

This reaction is facilitated by diphenylamine's relatively weak N–H bond, which has been determined to be $84.7 \pm 0.7 \text{ kcal mol}^{-1}$ (revised according to Ref. 101),¹⁶⁹ which is $2.5 \text{ kcal mol}^{-1}$ weaker than the O–H bond in phenol determined under the same conditions by the same method—REqEPR spectroscopy. The rate constant for this reaction has been determined by the inhibited autoxidation of styrene method to be 4.4×10^4 at 65°C ,¹⁷⁰ and more recently, $1.5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ at 50°C ,¹⁶⁹ which is a factor of 4 or so greater than for the reaction of phenol with peroxy radicals, owing primarily to the weaker bond. Reliable Arrhenius data for the reactions of diphenylamine and peroxy radicals are not available. However, it should be mentioned that aniline has $\log A = 6.3 \text{ M}^{-1} \text{ s}^{-1}$ and $E_a = 5.0 \text{ kcal mol}^{-1}$,¹³⁷ which is quite similar to that of phenol (see below). Aniline's lower reactivity ($k_{\text{inh}} = 1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ at 30°C)¹³⁷ is due to its stronger N–H bond of $\sim 90 \text{ kcal mol}^{-1}$.¹⁷¹

The role of a formal H-atom transfer mechanism in this reaction is supported by deuterium kinetic isotope effect studies, which yield $k_{\text{H}}/k_{\text{D}} = 3.0 \pm 0.5$ at 65°C .¹⁷⁰ Furthermore, a linear free-energy relationship is clear from the correlation of the logarithm of the inhibition rate constants of a series of ring-substituted diphenylamines with the

be much less susceptible to H-bonding effects than phenols, presumably due to a combination of both less H-bond acidity ($\alpha_{\text{H}}^2 = 0.324$ vs $0.4\text{--}0.6$ for most phenols) and sterics.¹⁷³ Recent theoretical calculations suggest a transition-state structure similar to those calculated for the reactions of phenols with peroxy radicals, whose geometry implies that the mechanism of the formal H-atom transfer could be described as a proton-coupled electron transfer.¹⁷⁴ As for phenols, the structure has significant orbital overlap between the π HOMO of one of the aryl rings and the π^* SOMO of the peroxy radical, suggesting that the electron is already partially delocalized from the diarylamine to the peroxy in the transition state. Presumably, the mechanistic interpretations for the diarylamines extend to the other classes of secondary aromatic amines widely used as antioxidants.

The subsequent chemistry of the diphenylaminyl radical makes aromatic amines arguably more interesting, and probably more useful, than phenols as radical-trapping antioxidants. In contrast with the reaction of phenoxyl radicals with peroxy radicals to yield nonradical products, the reaction of diphenylaminyl radicals with peroxy radicals leads to two radical products: the diphenylnitroxide and an alkoxy radical (61).^{175–177}

corresponding σ^+ substituent constants. The correlation affords a reaction constant $\rho^+ = -0.89$, which was initially interpreted as meaning that there was a highly polarized transition state for the formal H-atom transfer reaction,¹⁷² but it is also consistent simply with the trend in N–H bond dissociation enthalpies in this series of compounds, which yields $\rho^+ = -1.35$ by experiment and -2.5 by theoretical calculations.¹⁷¹ Kinetic solvent effect studies carried out using the peroxy clock methodology found an inverse linear relationship between the logarithm of the inhibition rate constant and the H-bond accepting ability of the solvent (quantified by Abraham's β_{H}^2 parameter), implying that the amine hydrogen must be free to be transferred in the rate-determining step of the reaction.⁸⁶ Diphenylamine was found to

This is formally an O-atom transfer reaction, but likely proceeds first by radical–radical combination followed by fragmentation of the weak O–O bond. Since alkoxy radicals are good initiators of autoxidation, this reaction does not result in a net chain-breaking reaction. However, since the product nitroxide will react with peroxy radicals eventually to give nonradical products (see the following section), the overall observed stoichiometric factor for diphenylamines is generally 2, as for phenols.

It must be qualified that the foregoing is true only at ambient temperatures. In fact, at high temperatures, such as those encountered in the operation of a combustion engine, diarylamines are characterized by much higher stoichiometric factors ($n > 40$). The prevailing hypothesis accounting

for this observation was advanced by Korcek and coworkers of the Ford Motor Company following the results of autoxidations of hexadecane (a model for motor oil) at 160 °C.¹⁷⁸ They found that when a diphenylnitroxide was used as an oxidation inhibitor, the corresponding diphenylamine was formed *in situ*. Furthermore, while the nitroxide was consumed rather rapidly in the oxidation, the amine built up to a substantial concentration before being consumed more slowly, suggesting that it may be the least reactive inhibitor in the system, and the rate of its regeneration is high. They went on to show that alkoxyamines derived from the diphenylnitroxide and chain-carrying hexadecyl radicals decomposed at temperatures above 120 °C to give the diphenylamine in very good yield. Hence, they proposed a catalytic cycle wherein the nitroxide that is generated by the reaction of the diphenylaminyl radicals with peroxy radicals traps an alkyl radical to yield an alkoxyamine, which decomposes to regenerate the original diphenylamine and produce a corresponding carbonyl compound. This catalytic inhibitory activity is summarized in Scheme 23.

The proposed catalytic cycle requires that the nitroxide trap an alkyl radical in competition with O_2 . Since both reactions are diffusion-controlled, this requires a substantial concentration of nitroxide.

Scheme 23 Korcek and coworkers' mechanism for the catalytic inhibition of oxidation by diarylamines.

Indeed, in their experiments, Korcek and coworkers used an amount of amine/nitroxide that is on the same order as $[\text{O}_2]$ (i.e., $\sim 1 \text{ mM}$), making this competition possible. It should be pointed out that, in motor oils, it is not unusual for the amine concentration to be at least this high.

3.2.2 Hydroxylamines

Hydroxylamines are known to have very weak O–H bonds and hence may be expected to be effective antioxidants. For example, TEMPO-H, the hydroxylamine of TEMPO, has an O–H BDE of $69.7 \text{ kcal mol}^{-1}$ —perhaps the weakest O–H bond to be accurately measured (REqEPR).^{179,180} Indeed, its rate constant for reaction with peroxy radicals (62) is $3.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$ at 30 °C in chlorobenzene, making it as reactive as α -TOH. The structurally similar 4-oxo-TEMPO-H was also reported to react quickly with peroxy radicals ($k_{\text{inh}} = 5.0 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ in *o*-dichlorobenzene),¹⁸¹ albeit a bit slower because of a slightly stronger O–H bond.¹⁸²

The reaction has a DKIE of $k_{\text{H}}/k_{\text{D}} = 3.0$ and is slowed slightly in H-bond accepting solvents (a factor of 1.3 on going from chlorobenzene to CH_3CN). The stoichiometric factor is 1. The reaction likely takes place by a PCET mechanism as for phenols and amines.¹¹²

While the thermodynamics and kinetics of their peroxy radical trapping activity indicate that this class of compounds should function effectively as inhibitors of oxidation, in practice their usefulness as antioxidants is limited by their facile oxidation to nitroxides by product hydroperoxides (63 and 64); as such, under some conditions they may operate as initiators. It should also be pointed out that the hydroxylamines themselves are not very stable, either in the presence or absence of oxygen. The two major products are the corresponding nitroxide and amine, formed in a 2 : 1 ratio, perhaps by the following reactions (Scheme 24):

Scheme 24 Anaerobic decomposition of hydroxylamines to the corresponding nitroxide (2 equiv) and amine (1 equiv).

Nonetheless, hydroxylamines can be stabilized by conversion to their corresponding hydrochloride salts, which are not active as antioxidants; in some cases, these water-soluble forms can release the “active” hydroxylamine in biological environments, and have been shown to possess antioxidant behavior both *ex vivo* and *in vivo* in human or other animal tissues.^{183–185}

3.2.3 Nitroxides

As discussed elsewhere in this encyclopedia, nitroxides have a rich chemistry revolving largely around their ability to trap alkyl radicals (see **Nitroxides in Synthetic Radical Chemistry** and **Nitroxide-Mediated Polymerization and its Applications**). The dogma of the

radical chemistry of nitroxides is that they are unreactive to O₂ or oxygen-centered radicals.³³ As such, for all but a handful of cases, they exhibit antioxidant activity simply by competing with O₂ for the chain-carrying alkyl radicals. The exception would appear to be electron-rich diarylamine-derived nitroxides, which give measurable rate constants for their reactions with peroxy radicals (e.g., 4,4'-dimethoxydiphenyl nitroxide, $k_{\text{inh}} \sim 5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$).¹⁸¹ While the mechanism has not been studied in detail, this may simply reflect the ease with which the peroxy can be reduced by electron transfer from the nitroxide, prompted by the formation of a stable corresponding oxoammonium ion (65). Alternatively, one could envision a Russell-type mechanism similar to that responsible for chain termination in uninhibited autoxidation. Diphenylnitroxides generally have stoichiometric factors of 1.

Recently, we revisited the reactivity of nitroxides with peroxy radicals.¹¹² In fact, we found that nitroxides could be *very* effective antioxidants, but only in the presence of a protic acid. For example, upon inclusion of 10 mM *p*-TsOH in the autoxidation mixture, the reaction went from proceeding with no visible inhibition period to one from which an inhibition rate constant of $1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ could be derived. Extension of the investigation to a series of organic acids of different strengths showed that the rate constants were clearly dependent on the $\text{p}K_{\text{a}}$ of the acid.

Further mechanistic studies revealed similarities with the previous examples. On changing the solvent from the relatively polar hydrogen-bond accepting (HBA) solvent CH_3CN to the relatively nonpolar non-HBA solvent chlorobenzene, the inhibition rate constants became larger. Furthermore, normal DKIEs were measured ($k_{\text{H}}/k_{\text{D}} = 2.2\text{--}2.4$), similar to those for hydroxylamines and aromatic amines. All in all, the acid dependence, kinetic solvent effects, and kinetic isotope effects point to a mechanism involving an unfavorable equilibrium ($\text{p}K_{\text{a}}$ of $\text{TEMPOH}^{+\bullet}$ is -5.8 in water) preceding a presumably facile H-atom transfer (66):

In an effort to help understand the goings on, we employed theoretical calculations, which indicated that protonated nitroxides are expected to have very weak O–H bonds, $\sim 10 \text{ kcal mol}^{-1}$ weaker than the corresponding hydroxylamines. Moreover, transition-state structures for reactions with peroxy radicals could be calculated, which had negligible activation energies, consistent with the observed fast kinetics.

Perhaps, most interestingly, in the presence of the weakest acids (i.e., acetic and benzoic acid), the antioxidant activity of TEMPO became catalytic. That is, the autoxidation remained essentially infinitely inhibited and TEMPO was not consumed in the reaction. This result is curious, as it implies that the oxoammonium ion derived from TEMPO is

reduced back to TEMPO in the reaction. The identity of the reducing agent remains a mystery, but it seems that the most likely candidate is the conjugate base of the acid (i.e., acetate or benzoate). This result presents an alternative, or perhaps complementary, explanation to the large stoichiometric factors observed in diarylamine-inhibited autoxidations at high temperatures since it is well known that carboxylic acids are formed as oxidation products under those conditions.

3.3 Thiols and Other Sulfur-Containing Compounds

Sulfur-containing compounds, particularly those in the S(II) oxidation state, can be effective reductants and most do react with peroxy radicals. For the most part, however, sulfur-containing compounds react in a two-electron fashion with hydroperoxides, and therefore have “preventive” activity as hydroperoxide-decomposing agents rather than chain-breaking activity. For instance, dialkyl disulfides are oxidized first to sulfoxides and

then sulfones upon reaction with hydroperoxides, giving rise to alcohols (67 and 68):

These reactions are acid-catalyzed, and are greatly facilitated by protic solvents.^{186,187}

3.3.1 Thiols

Thiols have a labile H atom and undergo H-atom transfer reactions with many radicals. In the case of peroxy radicals, the rates for these reactions

are modest (i.e., 10^3 – $10^5 \text{ M}^{-1} \text{ s}^{-1}$) and generally compete with the (two-electron) reaction of the thiol with a hydroperoxide under typical autoxidative conditions—nonradical chemistry leading to an alcohol and sulfenic acid as the primary product. The kinetics of the reactions of thiols with peroxy radicals is highly medium dependent; in aqueous

acid from the sulfoxide. Koelewijn and Berger have shown that di-*tert*-butylsulfoxide decomposes at or above 60°C to give rise to 2-methylpropanesulfenic acid and isobutylene (69), the former of which was estimated by them to react with the chain-carrying peroxy radicals in the autoxidation of tetralin with a rate constant of $\sim 1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$.¹⁹⁰

solution, the rates are higher, presumably because the thiolate (thiol $\text{p}K_{\text{a}} \sim 8$) reacts by electron transfer. In organic solution, the rates are lower, presumably since a HAT (or PCET) mechanism operates. The S–H BDE of alkylthiols is $\sim 89 \pm 1$.¹⁸⁸

The reaction of thiophenol and tertiary peroxy radicals has been characterized by a very low pre-exponential factor of $\log A = 4.5 \text{ M}^{-1} \text{ s}^{-1}$, which accounts for its modest measured rate constant of only $5.1 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ at 30°C , despite its extremely low activation energy of only $1.1 \text{ kcal mol}^{-1}$.¹³⁷ The low activation energy (compared to $5.2 \text{ kcal mol}^{-1}$ for phenol and $5.0 \text{ kcal mol}^{-1}$ for aniline) is likely the result of the weak S–H bond. Experimental S–H BDEs in thiophenol range from 78.7 to $83.9 \text{ kcal mol}^{-1}$,¹⁸⁹ which is lower than in phenol ($\sim 87 \text{ kcal mol}^{-1}$) and aniline ($\sim 89 \text{ kcal mol}^{-1}$). The reasons for the low A -factor are unclear, since it is anticipated that the mechanism of the reaction would be the same as for phenol and aniline: a PCET-type of formal HAT.

3.3.2 Sulfoxides

Sulfides, once oxidized to sulfoxides as above, can give rise to high radical-trapping activity. The mechanism has not been studied in detail, but is believed to rely on the elimination of a sulfenic

This high reactivity can be explained by the very low O–H BDE of sulfenic acids, an example of which has recently been determined experimentally to be $71.9 \text{ kcal mol}^{-1}$ (for the persistent 9-triptycenesulfenic acid).¹⁹¹ Theoretical calculations further suggest that alkanesulfenic acids react with peroxy radicals by a barrierless PCET mechanism, thereby implying that these reactions are diffusion-controlled.¹¹¹ Hence, the inhibition kinetics of sulfoxides should relate directly to their propensity to undergo elimination, which is particularly facile for hindered sulfoxides such as the di-*tert*-butylsulfoxide studied by Berger and Koelewijn (e.g., $k_{\text{elim}} = 1.8 \times 10^{-3} \text{ s}^{-1}$ for $\text{R} = \text{R}' = t\text{-Bu}$; $4.6 \times 10^{-5} \text{ s}^{-1}$ for $\text{R} = t\text{-Bu}$ and $\text{R}' = i\text{-Pr}$; and $6.3 \times 10^{-8} \text{ s}^{-1}$ for $\text{R} = t\text{-Bu}$ and $\text{R}' = \text{Me}$).¹⁹²

3.3.3 Thiosulfinates

Thiosulfinates, which are abundant in the plants of the *Allium* genus (e.g., garlic, onions, leeks, and shallots), can eliminate sulfenic acids readily owing to the weaker S–S bond in these compounds as compared to the S–C bond in sulfoxides. A particularly reactive thiosulfinate is allicin, the compound responsible for the odor and flavor of garlic. Allicin decomposes readily at room temperature, facilitated by the weak allylic C–H bond that is broken upon elimination of 2-propenesulfenic acid (70).¹¹¹

Most other *Allium* species contain thiosulfonates without equivalently activated C–H bonds, accounting for their lack of comparable antioxidant activity. An exception is the benzylic analog of allicin, *S*-benzyl phenylmethanethiosulfonate (BPT), which has also been demonstrated to be an effective antioxidant. *Peteveria alliacea*, the plant from which BPT was isolated, has been used as a medicine for centuries for essentially the same purposes as garlic. Interestingly, while BPT decomposes to yield phenylmethanesulfenic acid at much the same rate as allicin decomposes to yield 2-propenesulfenic acid, the decomposition of BPT is reversible (71), making it much more useful for applications.¹⁹³

4 SYNERGISTIC BEHAVIOR AND COOPERATIVITY AMONG ANTIOXIDANTS

In the design of commercial antioxidant formulations, whether it be to protect primary petroleum products, polymers, or foodstuffs, it is often convenient to use a combination of antioxidants. Furthermore, it is often that antioxidant additives with different mechanisms of action are chosen to make up the formulation, for example, preventive and chain-breaking, so as to guarantee that failure of one component will be compensated by the presence of the other(s). The same design is evident in the way antioxidant defense systems have evolved in aerobic organisms. Even though we focus our attention on only chain-breaking antioxidants, we note that several of them are found in combination in natural systems where they display an efficacy that is higher than that expected from the sum of the activity of the individual components. Therefore, they have *synergistic* behavior rather than simply *additive*.

In 1941, Columbic and Matill observed that the antioxidant activity of vitamin E (α -TOH) is enhanced in the presence of vitamin C (ascorbic acid).¹⁹⁴ Since then, several investigations have clearly demonstrated that these two vitamins show

a synergistic behavior. The most exhaustive studies have been reported by Niki *et al.*¹⁹⁵ in homogeneous solutions, and by Ingold and coworkers¹⁹⁶ in multilamellar phospholipid liposomes. Synergism with α -TOH has also been reported for ubiquinol in liposomes^{197,198} or in homogeneous solution,¹⁹⁸ and for several other antioxidants.⁵¹

4.1 Homogeneous Media

The inhibition kinetics of mixtures of antioxidants in homogeneous organic solutions has been

fully rationalized through co-inhibited autoxidation studies.^{59,199} When two antioxidants are added during the autoxidation of a substrate, they will react with chain-carrying peroxy radicals according to their individual inhibition rate constants (k_{inh}). In the case that one of the two compounds (AH) is significantly more reactive toward peroxy radicals than the other (CoAH), that is, $k_{\text{inh}} \gg k'_{\text{inh}}$, it could be expected that it is consumed first (via (10 and 11)), followed by the slower consumption of the antioxidant which reacts more slowly with peroxy radicals (via (72 and 73)).

This would result in an initial efficient inhibition of autoxidation, followed by a less efficient inhibition after consumption of AH, that is, a purely additive contribution of the two antioxidants, as illustrated in trace (d) of Figure 10. However, in some cases, the observed behavior is similar to

Figure 10 Typical oxygen uptake profile from the AIBN-initiated autoxidation of styrene in the absence of antioxidant (a), in the presence of a modest antioxidant CoAH (b), in the presence of a good antioxidant AH (c), in the presence of a 1 : 1 mixture of AH and CoAH where the kinetics are additive (d), or in the presence of a 1 : 1 mixture of AH and CoAH where CoAH regenerates the more reactive AH as in Scheme 24 (e).

that shown in trace (e) of Figure 10, with a slope of oxygen consumption close to that given by the best inhibitor (AH) and a duration of inhibition identical to that expected from the best inhibitor in case its concentration was equal to the sum $[AH]_0 + [CoAH]_0$, which implies a fully synergistic behavior. Synergism can be explained according to Scheme 25: that is, it is due to regeneration of AH from its radical at the expenses of CoAH.

Depending on the relative rates of regeneration, the inverse reaction (k_r/k_{-r}), and the rate of reaction of $A^\bullet$ with peroxy radicals, the antioxidant system will behave as purely additive ($\tau_{CoAH+AH} = \tau_{CoAH} + \tau_{AH} \approx \tau_{AH}$), purely synergistic ($\tau_{CoAH+AH} = 2\tau_{AH}$), or something in between. The efficiency of regeneration α can be determined from the stoichiometric coefficient measured for

the coantioxidant according to (73 and 74):

$$n_{CoAH} = R_i(\tau_{AH+CoAH} - \tau_{AH})/[CoAH] \quad (73)$$

$$n_{CoAH} = 2\alpha \text{ with } 0 \leq \alpha \leq 1 \quad (74)$$

In the case of a coantioxidant such as vitamin C, which normally scavenges only one peroxy radical, (74) becomes $n_{CoAH} = \alpha$. It has been shown that α is close to 1 when the regeneration is essentially irreversible, or when $k_r/k_{-r} \geq 1$: that is, when the coantioxidant has an O–H BDE lower than (or similar to) that of the more reactive antioxidant.

4.2 Heterogeneous Media

In heterogeneous media, the antioxidant and coantioxidant can be confined to two different compartments, that is, the aqueous phase and organic phase of micelles, or some other form of aqueous dispersion. A particularly relevant example is in cells, where the lipid-soluble antioxidants partition to the lipid bilayer (e.g., α -TOH) and the water-soluble antioxidants to the cytosol and/or extracellular matrix (e.g., ascorbate). As such, the interaction of the two antioxidants must take place at the interface, as illustrated in Scheme 26.

Scheme 25 Cooperativity between antioxidants in homogeneous solution.

Scheme 26 Cooperativity in heterogeneous systems.

When autoxidation occurs in the lipophilic region of such biphasic systems, synergism implies the exportation of the radical outside the “oxidizable compartment,” and into the aqueous environment where the coantioxidant is confined. An important example of this in a biological context involves the interplay between α -TOH and ascorbate in the inhibition of LDL oxidation. In the absence of ascorbate, α -TOH reacts with a chain-carrying lipid peroxyl radical (75); but in competition with the expected second chain-breaking reaction (76), the α -tocopheroxyl radical can react with a lipid in a chain transfer reaction, thereby mediating the chain reaction in lieu of inhibiting it. This has been referred to as *tocopherol-mediated peroxidation* (TMP).²⁰⁰ The reason (76) is slowed in this context relative to (77) is simply due to the vanishingly small steady-state numbers of radicals in the LDL particle. Since they are confined to the particle because of their solubility, they cannot diffuse to other particles in order to undergo either chain termination or (76).

When ascorbate is present in the aqueous phase, it can reduce the α -tocopheroxyl radical back to α -TOH, thereby subverting the TMP reaction (77). Besides the tocopherol/ascorbate couple, recent examples of synergism in heterogeneous media include those in liposomes between α -TOH and water-soluble 3-pyridinols,⁸⁰ or in water/chlorobenzene biphasic system between several organochalcogen-substituted phenols or 3-pyridinols and *N*-acetylcysteine.²⁰¹

5 OTHER RADICAL-TRAPPING ANTIOXIDANTS

5.1 Ascorbic Acid and Related Compounds

Ascorbic acid (vitamin C) is a potent water-soluble chain-breaking antioxidant whose primary role in biological systems is as a reducing cofactor, comprising the quenching of peroxyl and hydroperoxyl radicals in the aqueous intra- and extracellular environment. It also regenerates α -TOH and ubiquinol from their phenoxyl radicals at the lipid–water interface as illustrated in Section 4.2.²⁰²

Ascorbic acid (AscH_2) has a $\text{p}K_a$ of 4.1 in water, and therefore at physiological pH its antioxidant/reducing activity is to be ascribed to the ascorbate anion (AscH^-). Regardless, the radical-trapping antioxidant activity of both AscH_2 and AscH^- stems from their ability to react with peroxyl (or hydroperoxyl) radicals by formal H-atom transfer from the hydroxyl moiety in the 3- or 2-positions, respectively. The O–H BDEs of AscH_2 and AscH^- have been determined to be 78.0 and 71.8 kcal mol^{−1}, respectively, in water,^{150,203} and their respective rate constants for reaction with $\text{HOO}\cdot$ have been estimated as 1.6×10^4 and $1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$.²⁰⁴

Owing to the limited air stability of aqueous solutions of ascorbate and the insolubility of ascorbic acid in most lipid environments, ascorbic acid has found only limited industrial application. However, a number of lipid-soluble derivatives such as ascorbyl palmitate (Palm-AscH_2) and the isopropylidene $i\text{-Pr-AscH}_2$ have been employed as antioxidants.

Scheme 27 Antioxidant activity of ascorbic acid derivatives in acetonitrile.

In organic solvents (such as acetonitrile), they still behave as weak acids,²⁰⁵ and have similar antioxidant activity (e.g., in the protection of styrene) as AscH_2 and AscH^- with k_{inh} of 6×10^4 and $5 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ for the acid and conjugate base, respectively, as illustrated in Scheme 27.¹⁴⁹

Such a large difference in reactivity (~ 1000 -fold) between the neutral and anionic forms has been found to parallel the very large difference ($\sim 9 \text{ kcal mol}^{-1}$) in their O–H BDEs, which have been determined by REqEPR in *tert*-butanol as 81.0 and $72.2 \text{ kcal mol}^{-1}$ for Palm- AscH_2 and Palm- AscH^- , respectively. Similar values were also obtained from calculations.¹⁴⁹

5-Hydroxy-4-methyluracil (5-HMU), an immunotropic drug, is structurally related to ascorbic acid and has been found to undergo identical behavior with peroxy radicals: its k_{inh} in acetonitrile (at 30°C) was determined to be $1.5 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ and was found to be dramatically enhanced in the presence of bases, as a result of partial deprotonation of the ring N–H moiety at the 3-position ($\text{pK}_a = 8.5$ in water).²⁰⁶

5.2 β -Carotene and Related Compounds

β -Carotene has long been known as one of the most effective natural product quenchers of singlet oxygen ($^1\text{O}_2$), prompting its use as a protectant against skin photodamage. The predominant quenching mechanism is the physical quenching reaction, illustrated in (78), in which the carotenoid converts singlet oxygen into its ground (triplet) state by absorbing excess energy which is then thermally dispersed.²⁰⁷ It has been reported that a single

β -carotene molecule quenches up to 1000 molecules of $^1\text{O}_2$; however, it eventually undergoes oxidation (chemical quenching) to yield endoperoxides (via $4 + 2$ cycloadditions) and carbonyl fragments (from fragmentations of hydroperoxides), as depicted in Scheme 28.⁷⁶

β -Carotene also autoxidizes quite readily. When left in the dark at room temperature, solutions of β -carotene yield a multitude of oxygenated products comprising epoxides, conjugated aldehydes (including retinal, vitamin A), ketones, and dihydrofurans (Scheme 28).²⁰⁹ The initial product distribution undergoes further change in composition with time and yields more oxidized products (including carboxylic acids) with shorter and shorter hydrocarbon chain length. The autoxidation of β -carotene can be inhibited with α -TOH.²¹⁰

The mechanism of autoxidation of β -carotene is believed to be self-initiated, as illustrated in Scheme 29. The unusual mechanism involves the formation of a highly conjugated singlet biradical, which reacts with oxygen to form a triplet peroxy biradical, which can add to another molecule of β -carotene to form a peroxidic triplet biradical that can decompose via several different mechanisms, one of which involves the formation of an epoxide and an alkoxyl radical. In the presence of polyunsaturated lipids (e.g., in biological membranes), either the alkoxyl radical or the peroxy radical initially formed can initiate lipid peroxidation, meaning that β -carotene can act as a pro-oxidant in oxygen-rich lipid environments.

Scheme 28 Typical oxidation products formed by reaction of β -carotene with triplet or singlet oxygen at room temperature.

Scheme 29 Self-initiated autoxidation of β -carotene and initiation of lipid peroxidation.

On the other hand, β -carotene blood levels and the dietary intake of carotenoids have long been known to correlate inversely with the incidence of certain human cancers, leading to the suggestion that it plays a beneficial role in preventing lipid peroxidation as an antioxidant.²¹¹

Indeed β -carotene reacts rapidly with peroxy radicals, mainly by addition to the extended π system to yield a highly stabilized alkyl radical; however, the antioxidant behavior of β -carotene depends entirely on the fate of such a LOO- β C $\cdot$ radical, which in turn depends on the experimental and environmental conditions (Scheme 30). It was first shown by Burton and Ingold,²¹² and later confirmed by several other studies,²¹³ that β -carotene can protect oxidizable substrates such as polyunsaturated lipids from autoxidation/peroxidation, but only at low partial pressure of oxygen ($pO_2 > 150$ mmHg), while it loses its chain-breaking behavior or it can turn into a pro-oxidant at higher pO_2 .²¹⁴

This is due to the reversible addition of oxygen to the delocalized LOO- β C $\cdot$ radical to form a variety of peroxy radicals that might propagate the autoxidation chain or bring on rapid carotene autoxidation: this reaction, which is clearly favored by high concentrations of oxygen, competes with the antioxidant behavior that prevails at low pO_2 levels (Scheme 30).

Scheme 30 Antioxidant activity of β -carotene as a function of pO_2 .

Even when antioxidant behavior prevails, it is much less efficient than that of other natural antioxidants such as α -TOH, and only comparable to BHT in homogeneous solution.²¹⁵ Unlike other coantioxidants (e.g., ubiquinol, flavonoids, and ascorbic acid), β -carotene is unable to spare or regenerate α -TOH and, when used in combination, gives no synergism.^{215,216}

Indeed, the antioxidant role for β -carotene in biological systems is highly controversial. For instance, its dietary supplementation was found to be pro-oxidant in rats²¹⁷ and it has been found to afford no protection of LDL oxidation in humans.²¹⁸ Not surprisingly, in controlled clinical trials β -carotene produced an increase in mortality from cancer of the lungs,²¹⁹ a tissue exposed to the highest pO_2 among biological environments.

6 FUTURE PERSPECTIVES

Antioxidant research is a well-established and relatively mature field of application of free radical chemistry, which has benefited from about 60 years of investigation at all levels—from fundamental chemistry to applications in the petroleum and polymer sciences, biology, medicine, and food science. The chemistry of hydrocarbon (and lipid) autoxidation and the basic mechanisms by which they are inhibited by antioxidants are well understood. This is particularly true for phenolic antioxidants, whose chain-breaking antioxidant activity and structure–activity relationships have been characterized within a robust framework based on decades of detailed kinetic and thermodynamic studies. Nevertheless, some specific yet very relevant aspects appear to require further attention. One such aspect is the temperature dependence of their antioxidant behavior; most of the useful data is confined to a narrow temperature range, which is not particularly reflective of the conditions under which the compounds are most often applied (e.g., the protection of polymers during extrusion or motor oils under operative conditions) and has precluded the derivation of the Arrhenius parameters that govern their reaction with peroxy (and other relevant) radicals. These data would allow a deeper comprehension of the mechanism of such reactions, thereby facilitating the prediction of their antioxidant behavior under most conditions. The influence of the medium on phenolic antioxidant activity is another relevant issue that

has received somewhat less attention. Particularly, the occurrence of acid and base catalysis and their role in the antioxidant mechanism and kinetics has only recently been uncovered, and certainly merits further investigation—particularly relating to its implications on the biological role of both phenolic and nonphenolic antioxidants.

Unlike phenolic and phenolic-like antioxidants, comparatively little is known of the antioxidant chemistry of the other relevant compounds introduced above, such as diarylamines and nitroxides (both aliphatic and aromatic). The former have been employed extensively as antioxidants in commercial products and industrial processes; however, their significance has been largely overlooked by the academic scientific community, and a fundamental understanding of their chemistry is still lacking. Nitroxides, on the other hand, are possibly the most investigated radical species and have been used (or proposed to be of use) in an extraordinary variety of scientific and industrial applications. Nevertheless, the mechanism of their antioxidant behavior has long eluded recognition. The very recent discovery of their acid-catalyzed chain-breaking antioxidant activity has been a breakthrough in this area, and most certainly needs to be more thoroughly explored—particularly in light of the recent and rapidly growing awareness of the biological activity and potential pharmaceutical applications of these compounds.

Other important antioxidants that deserve further investigation are sulfur-containing compounds, in particular, sulfenic acids and their precursor thiosulfonates, as well as isothiocyanates and their precursor glucosinolates. Sulfenic acids and sulfinyl radicals are among the least well-characterized functional groups regularly encountered in organic chemistry because of the instability of most derivatives. Nonetheless, they figure prominently in the biochemistry of thiols, the most abundant antioxidants in biological systems, and in the biological activity of (dietary and medicinal) plant-derived disulfides and thiosulfonates. Indeed, further efforts should be made to provide a deeper understanding of their properties and reactivity.

The biological role and medicinal application of antioxidants, as well as their (nutritional) chemopreventive potential, still remains to be clarified, notwithstanding the major efforts devoted to this area of research in recent years. This is due, in part, to the continued uncertainty regarding

the role of oxidative stress and the intervention of free-radical intermediates in degenerative disease—from atherosclerosis to Alzheimer's—as well as cancer and aging. While there is overwhelming evidence that implicates oxidative stress in disease pathogenesis, antioxidant intervention has produced few tangible results that support a causative role. However, it should be pointed out that clinical investigations have so far focused on a relatively limited number of molecules, most notably β -carotene, vitamin E, and vitamin C. β -Carotene has been particularly popular in such experiments, presumably due to its facile monitoring by analytical techniques, leading to the common use of it as a key indicator for antioxidant content and dietary intake in epidemiological investigations correlating fruit/vegetable consumption and occurrence of chronic diseases. This has prompted a focus on β -carotene (and/or retinol, vitamin A) in the majority of clinical trials for dietary antioxidants on primary or secondary prevention of chronic diseases.²²⁰ The disappointing outcomes of the majority of clinical trials carried out to date have somewhat reduced the enthusiasm of the medical community toward the extraordinary potential that antioxidants have in therapy and prevention. However, it must be reiterated that investigations have been largely limited to a very small series of compounds, many of which have not proven to be particularly effective antioxidants in detailed investigations such as those described above (i.e., β -carotene). Indeed, despite their popularity, very few data are available on the bioavailability and metabolic fate of many phenolics, such as the polyphenolic flavonoids and isothiocyanates. Furthermore, to the best of our knowledge, no clinical trial has ever evaluated their activity in humans. The observation of lifespan extension in invertebrates as a consequence of antioxidant treatment,²²¹ among other exciting discoveries, continues to renew enthusiasm in antioxidant research, and clearly indicates that a deeper understanding of the role of oxidative stress and the intervention of chain-breaking antioxidants in disease pathogenesis and aging is one of the most important research topics of our time. The relatively recent recognition that reactive oxygen species contribute much more to cellular signaling in advanced organisms than previously thought²²² complicates things even further, but reinforces that much remains to be done.

Free Radicals and Metabolic Disorders

Guy Cohen, Yael Riahi and Shlomo Sasson

Department of Pharmacology, Institute for Drug Research, Faculty of Medicine, The Hebrew University, Jerusalem, Israel

1 INTRODUCTION

Free radicals are often formed and released following tissue injury owing to internal or external pathological processes. In many cases, the triggering role of free radical-generating systems has been associated with distinct pathological interactions. For instance, the ability of ionizing ultraviolet-A radiation to induce skin disorders, ranging from hyperpigmentation to melanoma, results from the generation of chemically reactive radicals in skin cells.^{1–4} Myocardial ischemic-reperfusion injury has been attributed to an enhanced generation of reactive oxygen species (ROS) in ischemic regions.^{5,6} Another example is Paraquat (*N,N'*-dimethyl-4,4'-bipyridinium dichloride)-induced symptoms of Parkinson's disease that result from irreversible nigrostriatal dopaminergic neurotoxicity owing to an impairment of mitochondrial function and production of ROS.^{7,8} In contrast to such well-defined processes, the metabolic syndrome consists of multiple disorders that collectively increase the risk of developing type-2 diabetes (T2D) and cardiovascular disease. A cluster of metabolic risk factors, foremost, hyperglycemia, hyperlipidemia, and obesity, is associated with overproduction of free-radical species, which play significant roles in promoting and exacerbating metabolic abnormalities and related complications.^{9–14} Currently, the prevalence of T2D has reached an epidemic proportions and the number of diabetic individuals in the year of 2030 is estimated to

exceed 300 million worldwide.¹⁵ Thus, attempts to identify new means to treat the disease are intense, and the elimination of free radicals in subjects exhibiting features of the metabolic syndrome is considered a prime target. Therefore, understanding the involvement of free radicals in these metabolic abnormalities is essential. It requires an integrative approach to elucidate the impact of free radicals on cellular and metabolic functions, organ cross-talk, hormonal control mechanisms, and neural regulation. This article focuses on the roles of hyperglycemia, hyperlipidemia, and obesity in free radical-induced metabolic impairments.

2 HYPERGLYCEMIA AND FREE RADICALS

The hallmark of diabetes is hyperglycemia, a condition in which fasting blood glucose levels remain high above the normal range. Several clinical prospective trials (i.e., Diabetes Control and Complications Trial and the UK Prospective Diabetes Study) have established that hyperglycemia promotes severe complications in peripheral organs such as nephropathy, retinopathy, neuropathy, or endothelial cell dysfunction followed by micro- and macrovascular complications.^{16–19} It is generally accepted that intermittent and chronic hyperglycemia mediate long-term modifications of intra- and extracellular macromolecules that in turn alter cells' functions and contribute to the development of peripheral complications.²⁰ Hyperglycemia

results from inadequate insulin secretion owing to pancreatic β -cell failure and/or peripheral insulin resistance. In both cases, high glucose-derived free radicals adversely affect pancreatic β -cells while contributing to the establishment of insulin resistance in the liver and skeletal muscles. The molecular mechanisms that favor free-radical production in living cells are complex and mostly involve nonenzymatic transformations of glucose coupled to an enhanced rate of protein glycation. Consequently, the increased abundance of free-radical species and excessive amounts of glycated proteins severely affect normal cell functions. Cells equipped with efficient antioxidative mechanisms are more protected against the hyperglycemic challenge than cells lacking an efficient radical elimination system. A typical example of the latter is pancreatic β -cells that poorly eliminate free radicals and therefore are exceptionally susceptible to free radical-induced damage.²¹

2.1 Etiology of Hyperglycemia

T2D results from two pathophysiological processes; impaired insulin biosynthesis and glucose-stimulated secretion from pancreatic β -cells and/or peripheral insulin resistance due to alterations in the insulin transduction mechanism of insulin-sensitive tissues.²² Gluco- and lipotoxicity are the two main conditions that adversely affect β -cell function.^{23,24} Numerous *in vitro* and *in vivo* studies have shown that prolonged exposure of β -cells to high glucose and/or lipid levels impair proinsulin synthesis and processing, insulin packaging in granules, and insulin secretion.^{23,25–28} Studies performed on animal models of diabetes and human subjects have shown that insulin resistance results from perturbations in the insulin transduction pathway mainly in the liver and skeletal muscles. Of the main defects found in these two tissues, impaired activation of the adapter protein insulin receptor substrate-1 and -2 (IRS1/IRS2) is the most common. Two main aberrations in IRS function have been identified; the first is an impaired tyrosine phosphorylation following the binding of these proteins to the activated insulin receptor. This reduces the ability of IRS proteins to interact with other transducing proteins in the pathway.^{29–32} The second is the initiation of the phosphorylation of serine moieties in IRS proteins, which directs them to an

enhanced degradation.^{33–40} Since IRS protein interaction with the activated insulin receptor constitutes an obligatory step in insulin transduction in cells, all insulin-mediated cellular functions are downregulated when IRS activation is impaired or its cellular content is reduced.⁴¹ The induction of insulin resistance in the liver compromises the ability of the hormone to suppress endogenous glucose production, to reduce gluconeogenesis, and to augment glycogenesis. Therefore, hepatic insulin resistance results in an uncontrolled and excessive glucose output that worsens hyperglycemia.^{42,43}

Postprandial hyperglycemia normally stimulates insulin secretion from β -cells, which in turn stimulates glucose uptake in skeletal muscles by recruiting the insulin-sensitive glucose transporter-4 to the plasma membrane of myotubes.^{44–46} Prolonged hyperglycemia and hyperlipidemia induce insulin resistance in skeletal muscles by similarly affecting IRS proteins' activity and turnover, thus abrogating the downstream insulin transduction pathway.^{47–49} These postreceptor defects impair insulin-stimulated glucose uptake by skeletal muscles and induce hyperglycemia. Furthermore, when combined with impaired insulin secretion from β -cells, the glucose uptake capacity of the skeletal muscle mass is further impeded and thus exacerbates hyperglycemia.⁵⁰

Gluco-lipotoxicity in β -cell refers to various processes that alter the insulin secretory function and survival of the cells when exposed to high glucose and free fatty acids (FFAs) levels. Numerous factors, including glucose, FFA, inflammatory cytokines, and adipokines have been implicated in impairing insulin biosynthesis and secretion and in inducing endoplasmic reticulum (ER) stress and β -cell death in diabetes.^{21,23,24,51,52} Consequently, the decreased insulin secretory capacity and reduction in β -cell mass in islets of Langerhans lead to hypoinsulinemia. When combined with peripheral insulin resistance, this condition further dysregulates peripheral glucose metabolism and aggravates glucose homeostasis.^{53,54}

2.2 Glucose-Derived Free Radicals

Diabetes and oxidative stress have long been connected.^{55,56} Several sources of free radicals, particularly through the mitochondrial respiratory chain and by the action of oxidative enzymes,

such as NADPH oxidase and lipoxygenases, have been identified.²⁰ Glucose autoxidation, protein glycation, and mitochondrial dysfunction are the main processes that overproduce free radicals in diabetes. Nonenzymatic enolization of monosaccharides along with a reduction of molecular oxygen under physiological conditions yields α -ketoaldehydes, hydrogen peroxides, and free-radical intermediates.^{57,58} Thornalley *et al.*⁵⁸ and Wolff and Dean⁵⁹ proposed the mechanism shown in Scheme 1, which describes the enolization of D-glucose and a sequential reduction of a transition metal and molecular oxygen to generate superoxide and ketoaldehyde. Dismutation of the superoxide anion generates hydrogen peroxide, which reoxidizes the transition metal, while reducing a hydroxyl radical. Initially, this model evolved from studies on oxygen consumption and free-radical involvement in glyceraldehyde autoxidation *in vitro*.⁵⁸

Evidence for this mechanism lies in the inhibition of ketoaldehyde formation from glucose in the presence of metal chelators, such as diethylenetriaminepentaacetic acid.^{60,61} This model has prevailed and is often presented in current relevant literature on monosaccharide toxicity. For instance, Okado-Matsumoto and Fridovich⁶² suggest that the tautomerism of open-chain aldoses to the corresponding enediols and their radicals, followed by their rearrangement to the

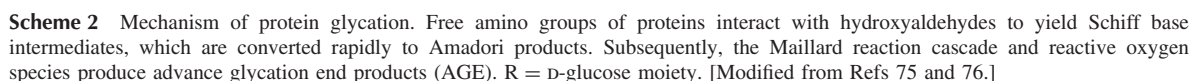

Scheme 1 Glucose autoxidation. D-Glucose enolizes and reduces a transition metal (M) and oxygen to form α -ketoaldehyde. Hydrogen peroxide, which is formed from superoxide anion dismutation, regenerates the metal catalytic oxidation state to produce hydroxyl radicals. R = D-glucose moiety. [Modified from Ref. 59.]

α,β -dicarbonyl derivatives, is the initial and pre-requisite step in the toxicity of short chain sugars. Using Fourier transform infrared (FTIR) spectroscopy, Yaylayan and Ismail⁶³ proposed a dimeric-water catalysis and sugar dimer-self catalysis of enolization. In this process, D-glucose autoxidizes slowly relative to glyceraldehyde; however, the amounts of ketoaldehyde formed in cells over prolonged periods of hyperglycemia may be substantial.⁵⁷ The quarter-of-a-century old debate between Harding and Beswick⁶⁴ and Wolff and Dean⁶¹ on theoretical and technical aspects further clarifies the model. Of a major interest is the association between autoxidation of glucose in the presence of transition metal ions in cells and the incorporation of glucose moieties into proteins.⁶⁵ Nonenzymatic protein glycation is the chemical reaction of reducing carbohydrates with amino moieties. Most D-glucose molecules in water are in the α/β pyranose/furanose ring structures; yet, a small fraction that remains in the open-chain aldehyde form can interact nonenzymatically with available amine residues in proteins.^{66,67}

Scheme 2 shows the interactions of free amino groups of proteins with carbonyl groups that yield Schiff base intermediates. Under physiological conditions, Schiff bases are converted to Amadori products. Subsequently, the Maillard reaction cascade is initiated and leads to the generation of stable carbonylated protein products.^{68,69} These glycation products can be oxidized by free radicals, including hydroxyl radicals, which are formed during glucose autoxidation, to give rise to different advanced glycation end products (AGEs).^{70–73} Apart from monosaccharides, such as D-glucose, AGEs are also produced from glucose metabolites such as glyceraldehyde, glycoaldehyde, methylglyoxal, and glyoxal.^{74,75} It is suggested that in addition to conformational and structural changes induced by carbonylation, protein fragmentation is also increased owing to the augmented generation of ROS through these autoxidative interactions.^{57,73}

Another source for oxidative stress in hyperglycemia is the overproduction of superoxide radicals by mitochondria. Brownlee and colleagues have suggested that overproduction of ROS by the electron-transport system under high glucose conditions underlies various cellular abnormalities typical to diabetes.^{77–79} The flow of electrons from donor molecules to electron acceptors enables the transfer of protons across the mitochondrial membrane,

The increased superoxide production has been associated with the activation of the polyol pathway, increased AGEs formation, activation of protein kinase C (PKC) isoforms, and overactivity of the hexosamine pathway.⁷⁷ The finding that the activity of the key glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH) is decreased in diabetic animals and patients have been linked to the abnormal activation of these pathways.⁸² The altered GAPDH activity in cells exposed to high glucose levels leads to the accumulation of glyceraldehyde 3-phosphate and upstream glycolytic metabolites. Figure 2 shows the pathways affected by these metabolites^{77,82}: the superoxide-induced activation of poly(ADP-ribose)-polymerase (PARP) adds polymers of ADP-ribose to GAPDH and reduces its enzymatic activity.⁸² Upstream to GAPDH, dihydroxyacetone phosphate generates diacylglycerol, an activator of PKC; triose phosphate is transformed to methylglyoxal, which is a main intracellular AGE precursor. Fructose-6-phosphate is transformed to UDP-*N*-acetylglucosamine, which increases modification of proteins by *O*-linked *N*-acetylglucosamine (GlcNAc). In addition, the increased glucose flux through the polyol pathway consumes NADPH and depletes the reduced glutathione pool in the

Figure 1 Mitochondrial ROS production. Complexes I and III in the electron-transport chain are the main free-radical generators. High glucose and FFA levels increase NADH/FADH₂ levels. Subsequently, the voltage gradient across the mitochondrial membrane increases up to a level that blocks complex III. Under these conditions, the degree of reduction of complex I increases and excess superoxide is generated by donating electrons to molecular oxygen. In addition, FFA release cytochrome c and has a mild uncoupling effect. [Modified from Ref. 80.]

Figure 2 Hyperglycemia and oxidative stress alter normal cell functions. Mitochondrial superoxide radicals activate PARP, which inactivates GAPDH. This results in the accumulation of glyceraldehyde-3-phosphate and of upstream glycolytic intermediates. These intermediates activate various PKC isoforms, increase the polyol- and the hexoseamine pathway fluxes, and augment the generation of AGEs. [Modified from Ref. 80.]

cells. In support of this model is the finding that the scavenging of superoxide radicals rescued GAPDH activity under hyperglycemia condition and corrected the above-mentioned pathways.^{77,83}

2.3 AGE-RAGE-Induced Free-Radical Generation

Intra- and extracellular formation of AGEs underlie the initiation and progression of peripheral diabetic complications. Levels of Amadori and AGE products in mammalian tissues are increased under prolonged hyperglycemia. Glycation and AGEs formation occur extra- and intracellularly. Some AGEs function as activating ligands for receptors for AGEs (RAGE) and operate distinct transduction pathways.^{84,85}

A number of plasma membrane receptors that bind various types of AGEs have been identified and characterized.^{20,86–91} These receptors are ubiquitously expressed and their AGE multiligand specificities have been unraveled.^{20,85,92} Among the AGE-RAGE-dependent cellular effects, the activation of inflammatory signaling is of interest: activated RAGE induces mitochondrial-dependent ROS production and NADPH activation followed the activation of NF- κ B.^{93–97} Several studies have suggested that the activation of NADPH oxidase requires PKC β 2-dependent translocation of subunit p47^{phox} to the plasma membrane and the formation of an active complex with p22^{phox} subunit.^{20,97,98} Other NF- κ B-dependent mechanisms have also been proposed, such as increased expression of inducible nitric oxide synthase (iNOS), cyclooxygenase 2 expression, vascular cell adhesion molecule (VCAM), intercellular adhesion molecule (ICAM), and monocyte chemotactic protein (MCP-1).^{99–104} In addition, a role of Toll-like receptor in these interactions has recently emerged.^{105–107} AGE-modified proteins have also been shown to facilitate the degradation of eNOS.¹⁰⁸ Other cellular processes that are altered by AGE-modified proteins in various types of cells include cell proliferation, differentiation, apoptosis, angiogenesis, generation of inflammatory cytokines, and the production and secretion of chemokines.^{20,104,109–114}

The levels of glycated and oxidized lipoproteins are significantly increased in diabetic individuals.^{20,115–118} Lipoprotein glycation is accompanied with oxidation due to the generation

of free radicals during the glycation process.¹¹⁹ Consequently, the metabolic degradation and clearance of VLDL and LDL is impaired and leads to hyperlipidemia, accelerated atherosclerosis, inflammatory signaling, endothelial cell dysfunction, mitogenic effects on vascular smooth muscle cells, foam-cell formation, alteration of platelet function, and pro-coagulant activity.^{20,115,120–126}

The glycation of insulin B-chain at the amino-terminal phenylalanine renders the hormone inactive; yet, although such insulin species were identified in islets of normal and diabetic animal, due to the rapid turnover of the hormone, the impact of this phenomenon on peripheral insulin action is not clear.^{127–130}

The glycation of the N-terminal valine amino group of the β -chain in hemoglobin generates hemoglobin-A1c (HbA1c). This modified protein is used as a biomarker to monitor glycemic control in hyperglycemic individuals. A HbA1c level below 6% is considered normal, while higher levels are indicative of short- to long-term hyperglycemic episodes.¹³¹ Similar to HbA1c, the circulating levels of glycated albumin reflect the glycemic control of hyperglycemic individuals.¹³² Some biological effects of glycated albumin have been linked to proinflammatory signaling, endothelial cell dysfunction, or glomerular nephropathy.^{20,133–136}

These observations indicate that protein glycation, AGEs generation, and the activation of RAGE and RAGE-like receptors are closely involved in the pathophysiology of diabetes and diabetes-related complications. The endothelial cell monolayer in blood vessels is severely affected upon exposure to glycated and AGE-modified LDL. The primary lesions in blood vessels, which promote the formation of atheromatous plaques, have been associated with AGE-induced permeability of the endothelial cell monolayer and with increased chemotactic interactions of monocytes followed by their transcytosis and formation of foam cells.^{119,137} AGE-modified proteins also contribute to the increased incidence of arterial stiffening and restenosis that are common in diabetic patients and appear at younger ages than in the general population.^{20,138–141}

Exposure of the retina to AGE-modified proteins activates microvascular endothelial cells and neoangiogenesis and thrombogenesis^{142–144} along with growth arrest and apoptosis of resident pericytes.¹⁴⁵ Glomerular nephropathy in diabetes

involves thickening of the basement membrane and its interaction with mesangial cells, endothelial cells, and podocytes.^{146,147} These pathological processes are prevented by inhibitors of AGE formation and RAGE blockade.^{142,148–150} AGEs and RAGE also contributed to the development of diabetic neuropathy by causing axonal degradation and demyelination of peripheral nerves. Impaired wound healing in diabetes also involves AGEs and RAGE and alteration in the inflammatory interactions that participate in the healing process.¹⁵¹ The AGE–RAGE–NF- κ B axis has been shown to mediate inflammatory interactions and macrophage invasion associated with these complications.^{152–155}

2.4 Reactive Nitrogen Species

Nitric oxide (NO) and peroxynitrite (ONOO[−]) are the common reactive nitrogen species (RNS). The enzyme nitric oxide synthase (NOS) releases NO radical from L-arginine. Various isotypes of the enzyme are expressed in a cell-specific manner, such as eNOS in vascular endothelial cells and the iNOS in activated macrophages. In the vascular wall, NO mediates vasodilation by relaxing the smooth muscle cells layer, whereas the iNOS-derived NO participates in inflammatory defense mechanisms. The NOS cofactor tetrahydrobiopterin (THB) is particularly susceptible to inactivating interaction, mostly with products of lipid peroxidation, such as 4-hydroxynonenal (4-HNE, see below). Under these circumstances, the lack of THB uncouples NOS that then generates superoxide radicals.¹⁵⁶ Nevertheless, it is not fully clear to what extent RNS play significant roles in obesity and diabetes.¹⁵⁷ While some studies report increased levels of NO metabolites in diabetic individuals,^{158,159} others show significant decrease in NO bioavailability in obesity and diabetes. Several mechanisms have been suggested to explain the latter observations, including reduced NOS expression and function and NOS uncoupling.^{156,160,161}

3 FATTY ACIDS AND FREE RADICALS

Hypertriglyceridemia, low HDL-cholesterol concentration, and high levels of apolipoprotein B-containing lipoproteins are considered

major atherogenic factors in the metabolic syndrome.^{162–165} A significant source for the production of ROS in cells is nonesterified long-chain FFA (and their metabolites).¹⁶⁶ The levels of FFA in plasma and in cells increase under specific physiological conditions, such as restricted nutritional consumption or starvation that mobilize FFA from the triglyceride storage compartment in adipose tissues to peripheral oxidation to meet the organism's energy demands.¹⁶⁷ Hyperlipidemia may also result from genetic abnormalities that alter the structure and function of lipoprotein lipase, LDL receptors, or apolipoproteins.^{168–171} Obesity and diabetes are considered major risk factors in the development of secondary (acquired) hyperlipidemia.^{172–176} Two major metabolic disturbances are associated with the augmented availability of FFA: excessive ROS production and lipid peroxidation. Mitochondrial uncoupling and inhibition of the respiratory chain are the main reasons for FFA-induced ROS production in cells. ROS-induced peroxidation of polyunsaturated fatty acid (PUFA) results in the generation of bioactive aldehyde species, which can act as signaling molecules, on one hand, or cytotoxic agents, on the other.^{156,166,177,178}

3.1 Etiology of Increased Circulating FFA Levels

Clinical studies over the years have demonstrated that elevated plasma FFA levels in T2D patients are common and predictive of the progression of the disease from the pre-diabetic state to overt disease.^{179,180} Normally, the release of FFA from adipose tissues is well-regulated and suits the energy demand of peripheral tissues. This is common when glucose availability to peripheral tissues is limited (e.g., starvation) or when glucose transport and utilization are impaired owing to insulin resistance and downregulation of the glucose transport system in insulin-sensitive- and other tissues.^{181–183} In addition, increased adiposity coupled with insulin resistance in adipose tissues result in an excessive release of FFA, far above the peripheral need.¹⁸⁴ Metabolic overloads, such as overfeeding, hyperglycemia, and/or hyperlipidemia, result in the enlargement of adipocytes, ER stress, hypoxia, and production of ROS, which contribute to the development of insulin resistance in adipocytes.^{185,186} Normally, insulin is a potent

antilipolytic agent in adipocytes through the inhibition of hormone-sensitive lipase that hydrolyzes stored triglyceride to FFA.¹⁸⁷ The loss of this regulatory function in insulin-resistant adipocytes leaves the enzyme free to interact with its positive effectors, catecholamines, and ACTH, resulting in an enhanced TG hydrolysis and increased release of FFA to the circulation.

3.2 Fatty Acids and Mitochondrial Free-Radical Production

FFA can interact with components of the respiratory chain and reduce the rate of the electron transport, which results in an enhanced superoxide anion generation, as suggested in the model proposed by Schönfeld and Wojtczak¹⁶⁶ (Figure 1). FFA inhibit, directly or indirectly, complexes I and III of the electron-transport chain and induce “electron leak” followed by one-electron reduction of molecular oxygen to superoxide anion.^{188–192} It is assumed that increased inner membrane fluidity in the mitochondrion due to FFA incorporation drives this phenomenon.^{193,194} FFA in the outer side of the membrane can interact with cytochrome c and dissociate it from the complex it forms with cardiolipin. The depletion of cytochrome c from the mitochondria interrupts the electron flow from complex III to complex IV.^{195–197} The release of cytochrome c is also associated with the induction of apoptosis in the affected cells.^{198,199} Finally, it is also assumed that increased inner membrane fluidity in the mitochondrion due to FFA incorporation has mild uncoupling effects, which is accompanied with superoxide anion generation.^{193,194} In addition, a role for acyl-CoA thioesters in the generation of ROS in the mitochondrion has been proposed: these compounds, which are the metabolically active forms of FFA, inhibit the adenine nucleotide translocase and di- and tricarboxylate translocases,^{200–202} resulting in the inhibition of ADP/ATP exchange across the inner membrane and subsequently enhance ROS production. Others have shown that these fatty acid thioesters increase the transmembrane potential ($\Delta\psi_m$) and lower the redox state of coenzyme Q, which also results in the generation of mitochondrial superoxide radicals.^{203,204}

Ceramides are amides of sphingosine and long-chain fatty acids, which are abundant in biological membranes. Recently, signaling properties of

ceramides and their derivatives (e.g., ceramide-1-phosphate, glycosyl-ceramide, and sphingosine-1-phosphate) in the regulation of inflammation, apoptosis, proliferation, and differentiation have been described.^{205–208} The biological availability of these mediators depends on the rate of hydrolysis of sphingomyelin through the action of sphingomyelinases.²⁰⁸ It has been found that natural long-chain ceramides exhibit a direct inhibitory effect on complexes I and III activity and release cytochrome c from mitochondria, thus contributing to ROS production.^{208,209} By these interactions, ceramides were associated with mitochondrial ROS generation following hypoxia, glucose depletion or by exposure to tumor necrosis factor- α (TNF- α).^{210,211}

3.3 Fatty Acids and Peroxisomal Generation of Free Radicals

Peroxisomes contain enzymes for α - and β -oxidation of fatty acids.^{21,212,213} Peroxisomal β -oxidation differs from the mitochondrial process in substrate specificity and function.²¹ Members of the ABC transporter family in peroxisomes mediate the transport of thioesters of these long-chain fatty acids (C17–C24)²¹⁴ that are preferably metabolized in there.²¹² Specific peroxisomal acyl-CoA synthetases shorten long-chain fatty acids to shorter acyl-CoAs that can then be transported to mitochondria via the carnitine palmitoyl-transferase (CPT)-1/2 and become fully subjected to oxidation. Unlike the mitochondrial electron-transport chain, in which the FAD is the acceptor, the electrons generated in peroxisomal β -oxidation are transferred to molecular oxygen and generate hydrogen peroxide.^{213,215} In addition, other peroxisomal enzymes, such as α -hydroxyacid oxidase, pipecolic acid oxidase, polyamine oxidase, and ureate oxidase, generate hydrogen peroxide, while the peroxisomal xanthine oxidase generates superoxide anions.²¹³

These peroxisomal reactions generate substantial amounts of hydrogen peroxide.²¹⁶ The latter is normally scavenged by peroxisomal oxidoreductase catalase.²¹ However, in cases when the expression of catalase is reduced or the enzyme is inhibited by posttranslational modifications (e.g., glycation), ROS production markedly increases, as occurs in pancreatic β -cells.^{217,218} The excessive

availability of FFA, which exceeds the mitochondrial oxidative capacity, promotes peroxisomal β -oxidation and increases the generation of toxic radicals.²¹

3.4 Fatty Acids and NADPH Oxidase-Mediated Superoxide Radical Generation

FFA are a known activators of members of the NADPH oxidase (NOX) family. These are transmembrane enzymatic complexes that transfer electrons across the membrane while generating superoxide radicals.²¹⁹ Members of the NOX family are involved in ROS-mediated defense mechanism and inflammation, such as in killing microbial virulence factors, senescence, and cell death.²¹⁹ Recent studies have shown that various NOX complexes are also involved in the etiology of metabolic disorders. For instance, NOX-derived ROS in the adipose tissue participate in the development of insulin resistance and the production and secretion of proinflammatory cytokines.^{220–222} Vascular NOX complexes are a major source of ROS in the vascular system, leading to eNOS inactivation, extracellular matrix modifications, endothelial cell dysfunction, smooth muscle cell proliferation, followed by aortic media hypertrophy, atherosclerosis, hypertension, cardiac hypertrophy and fibrosis, and ultimately diabetic cardiovascular disease.^{223–246} A major source for hepatic NOS-derived ROS is the specialized tissue macrophages, Kupffer cells, which are activated by exogenous factors such as bacterial endotoxins or nutritional factors (e.g., lipids, ethanol). ROS induce hepatic dysfunction including apoptosis, production of collagen in hepatic stellate cells, and in liver ischemia-reperfusion injury.^{229, 247–257}

The model proposed by Schönfeld and Wojtczak¹⁶⁶ (Figure 3) describes how FFA activate the NOX complex to generate superoxide radicals, by inducing conformational changes in the p47^{phox} subunit and facilitating its interaction with the p22^{phox}, which drives forward superoxide generation. In addition, due to their amphiphilic nature, FFA capably interact with and improve the interaction of the Rac GTPase and cytochrome b₅₅₈ and increase the affinity of the complex to oxygen.^{258–262}

Figure 3 Sites of interaction of FFA with the NADPH oxidase complex. The active NADPH oxidase complex is formed by assembling membrane-associated subunits (p22^{phox} and gp91^{phox}) and cytosolic subunits (p47^{phox}, Rac, p40^{phox}, p67^{phox}). Solid lines and arrows indicate electron (e^-) transfer. FFA interact with p47^{phox} and facilitates its interaction with the p22^{phox}, which drives forward superoxide generation. 3.5 Lipid Peroxidation

The term *lipid peroxidation* describes series of enzymatic and nonenzymatic reactions that generate many products with diverse physiological and pathophysiological functions. The peroxidation of PUFAs generates a group of reactive aldehydes, known as 4-hydroxyalkenals, which can act dose dependently as signaling molecules or as cytotoxic agents. Increased production of ROS in cells intensifies the peroxidation of PUFAs. Several alternative chemical mechanisms for the generation of 4-hydroxyalkenals from *n*-3 and *n*-6 PUFAs have been proposed.^{263–268} Niki has recently summarized and reviewed this topic²⁶⁹ (see also **Lipid Peroxidation**). The initiation step is mediated by hydroxyl radical- and lipid peroxyl radical-mediated abstraction of bisallylic H atom from *n*-3 and *n*-6 unsaturated fatty acids or their lipoxygenase-derived hydroperoxy metabolites to form conjugated diene lipid hydroperoxides. These products further undergo intramolecular rearrangement and chain-breaking reactions to generate various saturated and unsaturated aldehydes, among which unsaturated 4-hydroxyalkenals mediate critical biological and cytotoxic functions.

Figure 4a¹⁷⁸ outlines the nonenzymatic peroxidation pathways that lead to the production of 4-hydroxy-2*E*-hexenal (4-HHE) and 4-hydroxy-2*E*-nonenal (4-HNE). The generation of 4-HNE and 4-hydroxy-2*E*,6*Z*-dodecadienal (4-HDDE), shown in Figure 4b,¹⁷⁸ begins with 12- and 15-lipoxygenases (12-LO and 15-LO)-mediated conversion of *n*-6 PUFAs to their respective hydroperoxy metabolites. While 4-HDDE is exclusively generated from 12-hydroperoxyeicosatetraenoic acid (12-HpETE), the peroxidation product of 15-HpETE (the 15-LO metabolite of arachidonic acid (AA) and other *n*-6 PUFAs) is 4-HNE.²⁷⁰ Free radicals increase the flux of PUFAs and their hydroperoxy metabolites in two ways: first, the H atom abstraction and interaction with oxygen to form lipid peroxyl radicals which promotes the nonenzymatic cascade up to the generation of 4-hydroxyalkenals.^{264,265,267,268,271} The second mechanism is a free radical-mediated inactivation of the enzyme glutathione peroxidase (GPx), which transforms LO-derived hydroperoxy metabolites of AA to their respective biologically active hydroxy metabolites (e.g., 12-hydroeicosatetraenoic acid, 12-HETE).²⁷² ROS-induced inactivation of GPx

increases the flux of hydroperoxy metabolites of lipoxygenases through the peroxidation cascade.²⁷³

Figure 5 summarizes these processes in the transformation of AA to 4-HNE and 4-HDDE: following the hydrolysis of AA from the *sn*-2 position of phospholipids by the action of members of the phospholipase A2 family, the enzymes cyclooxygenase-1 and the inducible cyclooxygenase-2 catalyze the transformation of AA to prostaglandin H2, the precursor substrate of prostaglandin and thromboxane synthases. AA is also transformed to various ETEs and HETE s through the *cytP*₄₅₀- ω -hydrolase- and *cytP*₄₅₀-epoxidase pathways. The metabolism of AA by 12-LO and 15-LO results in its transformation to 12-HpETE and 15-HpETE, respectively. These are further reduced by GPx to the biologically active 12-HETE and 15-HETE. The peroxidation of AA, 12-HpETE, and 5-HpETE begins with the H atom abstraction through the chain of reaction that generates the respective 4-HNE and 4-HDDE. This model suggests that the cell-specific generation of the various 4-hydroxyalkenals depends on the pattern of expression of the various lipoxygenases and the relative abundance of the ω -3- and ω -6 PUFAs in the cells. The other factor that controls the cellular levels of 4-hydroxyalkenals is the cell's capacity to transform them to their carboxylic form by the

Figure 4 Peroxidation of polyunsaturated fatty acids. (a) Nonenzymatic generation of 4-HHE and 4-HNE from *n*-3 and *n*-6 PUFAs, respectively. (b) Lipoxygenase-initiated peroxidation of *n*-6 PUFAs and the generation of 4-HNE and 4-HDDE. [Reproduced from Riahi *et al. Am J Physiol Endocrinol Metab.*, 2010 [178]. The American Physiological Society, used with permission.]

Figure 5 Metabolism and peroxidation of arachidonic acid. Cyclooxygenase (COX)-, 5-lipoxygenase (5-LO)-, CYP450-, and hepxilin epoxide hydrolase (HXEH) mediate the transformation of arachidonic acid to the respective metabolites (gray). The enzymes 12-lipoxygenase (12-LO) and 15-lipoxygenase (15-LO) transform arachidonic acid to 12- and 15-hydroperoxyeicosatetraenoic acid (HpETE); downstream, glutathione peroxidase (GPx) transforms them to the respective 12- and 15-HETE (blue). Reactive oxygen species (ROS)-induced lipid peroxidation (LPO) of 12- and 15-HpETE results in the generation of 4-HNE and 4-HDDE (red). These reactive aldehydes interact with and inactivate GPx, leading to an increased rate of 12-HpETE and 15-HpETE peroxidation. The neutralization reactions of 4-HNE and 4-HDDE to the corresponding 4-hydroxynonenal (4-HNA) and 4-hydroxydodecadienoic acid (4-HDDA) are mediated by fatty aldehyde dehydrogenase (FALDH) and glutathione-S-transferase (GST) (green). [Reproduced from Ref. 177. Copyright Informa Healthcare. Reproduced with permission.]

action of fatty aldehyde dehydrogenase (FALDH) or by their conjugation to glutathione by the action of glutathione-S-transferase (GST). Covalent interactions of 4-hydroxyalkenals with GPx inactivate this enzyme and increase the flux of AA, 12-HpETE, and 5-HpETE through the nonenzymatic peroxidation cascade.

It is believed that *n*-3 PUFAs are a beneficial dietary supplement. Thus, of a particular interest is the *fat-1* mouse model that expresses the *Caenorhabditis elegans* 6-desaturase (*fat-1*) gene, which converts *n*-6-PUFAs to *n*-3 PUFAs.²⁷⁴ These mice exhibit improved cellular and organ functions, such as prevention of neoplasia,²⁷⁵ improved glucose homeostasis,²⁷⁶ and efficient anti-inflammatory interactions.²⁷⁷ Nonetheless, recent studies suggest

that excess of *n*-3 PUFAs and their subsequent transformation to 4-hydroxyhexenal (4-HHE) may be harmful. For instance, intraperitoneal or intravenous administration of high doses of 4-HHE resulted in peritonitis and liver damage, respectively.²⁷⁸ Some studies showed that *fat-1* mice were immunologically compromised and exhibited impaired resistance to tuberculosis.²⁷⁹ A photooxidative retinal damage in these mice was positively correlated to the level of the docosahexaenoic acid and the extent of lipid peroxidation.²⁸⁰

We have recently reported that the generation of 4-HDDE increases significantly in vascular endothelial cells exposed to high glucose levels²⁸¹ and that 4-HDDE is a potent activating ligand of the peroxisome proliferator-activated

receptor δ (PPAR δ). Similarly, Coleman *et al.*²⁸² found that 4-HNE was an intracellular agonist of PPAR δ in 3T3L1 preadipocytes. These findings are particularly important in view of the various metabolic and regulatory functions PPAR δ mediates, such as anti-inflammatory interactions,²⁸³ repression of inflammatory gene expression in macrophages,²⁸⁴ increased oxidative capacity of FFA in mitochondria,^{285,286} augmented cholesterol export, and regulation of glucose metabolism and insulin sensitivity.²⁸⁷

Many studies on beneficial and detrimental effects of 4-HNE have appeared in recent years^{267,269,288–295} and some other signaling targets of 4-HNE have been suggested, such as c-Jun N-terminal kinase (JNK),²⁹⁶ p38 mitogen-activated protein kinases (p38MAPK),²⁹⁷ cell cycle regulators,²⁹⁸ and protein kinase- β and - δ (PKC β and PKC δ).^{299,300} Nonetheless, these studies do not claim that 4-HNE is a classical ligand of these proteins. In fact, these effects may result from the capacity of 4-HNE to form covalent adducts with macromolecules and evoke variable physiological and pathological responses. For instance, Niki and colleagues^{269,301,302} showed that nontoxic levels of 4-HNE improve the antioxidant defense of cells by activating NF-E2-related transcription factor-2 (Nrf2) and increasing the expression of antioxidant enzymes. However, high 4-HNE levels inhibit and/or inactivate various enzymes (oxidoreductases, transferases, hydrolases, lyases, and isomerases), membrane proteins (carriers, receptors, ion channels, transporters), and cytoskeletal proteins.²⁸⁸ Of interest is the capacity of 4-HNE to increase production of ROS by covalently modifying thioredoxin-1 and compromising its antioxidant function.³⁰³ These and similar effects of 4-HNE are also related to the induction of NF- κ B-mediated proinflammatory effects^{304,305} and stress-induced apoptosis.³⁰⁶

High levels of 4-HNE have been linked to mitochondrial dysfunction. Some key proteins in the mitochondrial respiratory chain (e.g., the adenine nucleotide translocator (ANT) or cytochrome c oxidase) and enzymes in the TCA cycle (α -ketoglutarate dehydrogenase and isocitrate dehydrogenase) are particularly susceptible to 4-HNE-induced inactivation.^{307–311} These interactions further modify the electron-transport chain and augment ROS production in the affected mitochondria.

It should be emphasized that 4-hydroxyalkenals also bind covalently to membrane phospholipids and cholesterol.^{272,312,313} These interactions distort the normal lipid bilayer structure of membranes, their integrity, fluidity, and consequently their functions. In addition, the oxidation of LDL is mediated by radical-induced formation of hydroperoxides and 4-HNE.^{314–316} The resulting oxLDL is involved in macrophage activation, foam-cell formation, and atherosclerosis.^{317–319} Oxidized LDL is taken up by macrophages via scavenger receptors (i.e., CD36, SR-A) that induce foam-cell formation in the intima of blood vessels.³²⁰ Therefore, 4-HNE is considered an atherogenic factor that contributes to the pathology of the metabolic syndrome. Oxidative stress in cells that predominantly express 12-LO leads to the generation of 4-HDDE (Figure 4b). Low levels of 4-HDDE may regulate various cell functions by interacting with PPAR δ ^{281,282}; however, an excessive production of 4-HDDE (as well as other 4-hydroxyalkenals) can result in covalent modifications of macromolecules and aberrant cell function, as was found in pancreatic β -cells³²¹ and the juxtaglomerular apparatus in the kidney.³²² Possibly, such effects of 4-HDDE may be found in leukocytes, platelets, and epidermal cells, prostate cancer cells, and selected neural cells, which express the 12-LO isotypes.³²³

The role of 4-hydroxyalkenals in diabetes has recently been reviewed.¹⁵⁶ Hyperglycemia initiates lipid peroxidation in cells owing to the overproduction of glucose-derived free radicals. Moreover, an increased expression of 12- and 15-LO in cells exposed to high glucose levels leads to an increased production of 12- and 15-HpETE, the precursors of 4-HNE and 4-HDDE, respectively. Clinical observations on increased levels of 4-HNE-modified albumin in type-2 diabetic patients support the role of glucose-induced lipid peroxidation in diabetes.³²⁴ Moreover, β -cell dysfunction and the development of macrovascular disease and the accelerated deterioration to atherosclerosis had been also associated with an elevated production of 4-hydroxyalkenals.¹⁵⁶

4 OBESITY AND OXIDATIVE STRESS

White adipose tissue, the predominant fat depot in man, is consisted of mature adipocytes and preadipocytes along with vascular endothelial cells,

macrophages, mast cells, and dendritic cells.³²⁵ Adipose tissue is distributed in multiple depots in the body, mainly subcutaneous, visceral, and ectopic fat (e.g., epicardial, perivascular, gonadal).^{326,327} The fat storage capacity in these depots is remarkably high and is associated with tissue hypertrophy and hyperplasia and is initiated by high calorie food intake and a combination of hormonal and signaling pathways that induce a proportional growth and differentiation of preadipocytes to mature adipocytes upon increased availability of fat.³²⁸ Hypertrophied and fat-laden adipose tissues suffer from local hypoxia, which induce local inflammation and apoptosis.^{329–331} In addition, the increased availability of FFA and glucose affect the electron-transport chain in mitochondria to generate ROS. Indeed, the inflamed phenotype in the adipose tissue is characterized with an increased production of free radicals, generated mainly by activated macrophages.³³² This oxidative stress, combined with the increased production and presence of inflammatory cytokines and elevated FFA, activates stress kinases in the adipose tissue, which further induces insulin resistance, increase expression of proinflammatory genes, and promotes ER stress.^{332–337}

4.1 The Secretome of Adipose Tissues

Metabolic, oxidative, and inflammatory signals regulate the secretory functions of mature adipocytes. The two prime adiposity signals secreted from nonobese and noninflamed adipose tissues are leptin and adiponectin. The expression of these two factors is inversely regulated; increased total body fat augments the expression of leptin and reduces the expression of adiponectin. The former interacts with hypothalamic food intake and energy expenditure centers and the latter contributes to whole-body insulin sensitivity, particularly in skeletal muscle.^{338,339} Obese adipose tissues secrete many other factors, such as IL-6, IL-8, chemerin, MCP-1, plasminogen activator inhibitor-1 (PAI-1), RANTES, resistin, retinol binding protein 4 (RBP4), TNF- α , or visfatin.^{338,340–342} Insulin resistance in skeletal muscles,^{339,343–345} vascular cell dysfunction,³⁴⁶ atherosclerosis,^{347,348} and peripheral inflammatory processes^{340,342,349} are induced by some of these secreted proteins.³²⁵ Chemotactic factors, such as MCP-1, recruit circulating monocytes. The inflamed and apoptotic environment in

the obese adipose tissue activates these recruited and resident macrophages and further intensifies inflammation.³⁵⁰

Monteiro and Azevedo³³² have recently suggested a comprehensive model on the interplay between obesity, inflammation, and the metabolic syndrome (Figure 6). It suggests that the metabolic stress in fat cells leads to increased ROS generation, overproduction of adipokines, and activation of stress kinases, which potentiate the transcription of inflammatory genes and induce insulin resistance. Adipocyte death due to necrosis and apoptosis attracts macrophages, activates them to further reinforce inflammation, ROS production, and secretion of inflammatory cytokines, while reducing the production and secretion of the anti-inflammatory adiponectin. FFA also interact with Toll-like receptors in adipocytes and further enhance the inflammatory response. In addition, FFA accumulate in the liver and alter fat and lipoprotein composition and function. Furthermore, FFAs also induce insulin resistance in skeletal muscles. This model also claims that fat affects intestinal permeability and microbiota, which may also be involved in the production of inflammatory cytokines that act peripherally.

4.2 Lipid Peroxidation in Obese Adipose Tissues

Lipid peroxidation in obese adipose tissues is augmented due to an increased availability of PUFAs and ROS. An adipose cell-specific PLA₂ (AdPLA₂), with a preference to *sn*-2-bound AA and linoleic acid in phosphatidylcholine, has recently been discovered in mature adipocytes,^{351,352} and its expression is upregulated following a high fat diet.³⁵³ AdPLA₂ increases the availability of PUFAs, AA in particular, which are transformed by lipoxygenases to the respective hydroperoxy derivatives. The oxidative environment in fat-laden and inflamed adipocytes then favors the generation of 4-hydroxyalkenals by initiating the peroxidation cascade, as described above. A strong support for this mechanism comes from the 12-LO-KO (knock-out) mouse, which does not develop low-grade inflammation when fed a high calorie diet. Moreover, despite adipose cell hypertrophy, 12-LO-KO

Figure 6 The cross-talk between obesity and inflammation. Overview of the complex interplay between obesity and inflammation in the metabolic syndrome: metabolic overload impact leads to the production of ROS and adipokines, as well as activation of kinases that potentiate the transcription of inflammatory genes and interfere with insulin signaling. Adipose cell hypertrophy induces cell apoptosis and death and chemotactic recruitment of activated macrophages, which further enhance the production of ROS and inflammatory cytokines, whereas the secretion of the anti-inflammatory adiponectin is reduced. Increased levels of SFAs, from the diet and lipolysis in adipose tissues, accumulate in the liver, among other organs. Fatty livers overproduce LDL and proinflammatory cytokines such as IL-6 of CRP. SFA also activate Toll-like receptors in adipocytes and further enhance the inflammatory response. In addition, increased FFA levels induce insulin resistance in adipose tissues, the liver, and skeletal muscles. Dietary fat also affects intestinal permeability and interacts with microbiota to generate inflammatory factors that act systemically. AP-1, activator protein-1; CRP, C-reactive protein; FFA, free fatty acids; IL-n, interleukins; IKK, inhibitor of NF- κ B kinase; Int, intestine; IR, insulin resistance; JNK, c-Jun N-terminal kinase; LDL, low density lipoprotein; M, microbiota; NAFLD, nonalcoholic fatty liver disease; NF- κ B, nuclear factor κ B; Oxs, oxidative stress; PKC, protein kinase C; SFAs, saturated fatty acids; TAG, triacylglycerols; TLR, Toll-like receptors; TNF α , tumor necrosis factor- α . [Reproduced with permission from [332].]

mice exhibit significantly lower macrophage infiltration and activation in the visceral adipose tissue, in comparison with the high calorie diet-fed wild-type mice.³⁵⁴ A role for 4-HNE in altering adipocyte functions has been established: adiponectin secretion was reduced and insulin resistance was induced in 4-HNE treated 3T3-L1 adipocytes.^{297,355,356} A deletion of the *mGsta4* gene created a mouse model with an impeded capacity to neutralize 4-HNE.^{297,355} High calorie diet induced adipose tissue hypertrophy and increased macrophages infiltration and activation to the adipose tissue in these GST-KO mice. Therefore, it is concluded that in addition to the role of an oxidative environment and ROS production, PUFAs peroxidation and the generation of 4-hydroxyalkenals also contribute to the development of the proinflammatory phenotype of adipose tissues.

5 FREE RADICALS AND DIABETIC COMPLICATIONS

Many studies have implicated increased oxidative stress, augmented lipid peroxidation, and altered antioxidant capacity of cells and organs in the development of obesity- and diabetes-related complications.¹⁵⁷ The major complications attributed to free radicals and lipid peroxidation products are peripheral insulin resistance that affects the liver, adipose tissues and skeletal muscles, β -cell dysfunction, protein modifications, membrane alterations, and extracellular matrix modifications which cause end-organ malfunctions, such as nephropathy, retinopathy, neuropathy, and impaired wound healing. Although free radicals and lipid peroxidation products share similar chemical interactions in various cell types, the outcome of these interactions

vary in a cell-specific manner leading to various complications.

5.1 Roles of ROS in Inducing Diabetic Complications

A major effect of ROS is the induction of insulin resistance by interfering with the insulin receptor-mediated signal transduction. The binding of insulin to the insulin receptor triggers the autophosphorylation of distinct tyrosine moieties in the intracellular domains of the receptor's β -subunits. Once phosphorylated, these subunits bind IRS proteins and the tyrosine-kinase catalytic domain of the receptor phosphorylates tyrosine moieties in the docked IRS molecules. The resulting complex recruits other proteins and the various pathways of insulin signaling are then activated, leading to cell-specific effects, such as translocation of glucose transporters to the plasma membrane of skeletal muscles or the inhibition of the hormone-sensitive lipase in adipocytes.^{357,358} The termination of the insulin receptor-mediated effects is achieved by dissociating IRS from the insulin receptor complex.

ROS play a key role in downregulating IRS interaction with insulin receptor by inducing serine phosphorylation in IRS proteins and their subsequent proteolytic degradation. It was shown³⁵⁹ that IRS1 content in adipocytes was markedly reduced following the induction of oxidative stress. Serine residue phosphorylation in IRS proteins is mediated by several Ser/Thr kinases, including mTOR, S6K1, and PKC γ and PKC ζ .^{157,360} The outcome of the phosphorylation of the serine moieties has been delineated. For instance, Ser³¹⁹ that is phosphorylated by PKC ζ ³⁶¹ disrupts the interaction between the insulin receptor and the phosphotyrosine-binding (PTB) domain of IRS1, thus impeding the insulin receptor signaling pathways. S6K1 (p70 ribosomal protein S6 kinase 1)-mediated serine phosphorylation of IRS1 is also upregulated by various stressors, including obesity, increased levels of FFA, TNF- α , and other ROS-producers.³⁶⁰ Similarly, JNK-induced phosphorylation of Ser³⁰⁸ uncouples IRS1 from the insulin receptor.³⁸

In addition, peripheral insulin resistance is also induced by adipocyte-derived factors.³²⁵ T2D is associated with reduced secretion of adiponectin, thus limiting its peripheral anti-inflammatory and

insulin-sensitizing effects. It has been suggested that a vicious cycle between insulin and adiponectin operates in T2D patients, in which hyperinsulinemia, which develops due to insulin resistance, suppresses adiponectin secretion, which further deteriorates peripheral insulin sensitivity.³⁶² Other molecular mechanisms linking ROS to the development of peripheral insulin resistance, such as ROS-dependent activation of JNK, p38, and IKK β , have recently been proposed.³⁶³

Endogenous and exogenous ROS induce β -cell dysfunction. Gluco-lipotoxicity in β -cells combines all known deleterious interactions caused by hyperglycemia and increased FFA levels. These interactions include glucose autooxidation, mitochondrial ROS production, activation of NADPH oxidase, nonenzymatic protein glycation, and RAGE-mediated effects or increased metabolite flux in the polyol and hexosamine pathways.^{24,59,364–366} Recently, it has been suggested that the expression and function of thioredoxin and thioredoxin-interacting (TXNIP) proteins is regulated in β -cells by glucose²⁴; specifically, the increased expression of TXNIP leads to oxidative stress resulting in β -cell apoptosis.^{367–373} Oxidative stress also induces ER stress in β -cells, which was associated with an adaptive response of the cells to the stressful conditions. However, prolonged ER stress can deteriorate to death promoting processes and demise of β -cells. The latter response may involve overproduction of ROS.^{374,375} This *double-edge* effect of ER stress and the unfolded protein response in β -cells has recently been described and discussed.^{24,376–378}

5.2 Roles of Lipid Peroxidation in Inducing Diabetic Complications

Protein carbonylation (by glycation or lipid peroxidation-induced adduct formation) causes multiple deleterious effects in cells and tissues. While the role of protein glycation in inducing such complications has been well-investigated and described,^{77,379–381} the role of 4-hydroxyalkenal-induced modifications in diabetes and obesity-induced complications is less recognized.

Various studies have alluded to a key role of 4-hydroxyalkenals in inducing β -cell dysfunction: an increased expression of 12-LO in islets

of diabetic rats was associated with an impaired insulin secretory function.³²¹ Overexpression of 12-LO in cultured INS-1E β -cells significantly reduced their glucose-induced insulin secretory capacity.³⁸² Conversely, 12-LO knockout mice maintained normal β -cell function when fed a diabetogenic high fat diet.³⁵⁴ It has been suggested³⁸³ that such reactive aldehyde species are involved in the destruction of rat pancreatic islet β -cells by cytokines.³⁸⁴ Pharmacological inhibition of 12-LO prevented cytokine-induced β -cell death.³⁸⁵ The marked susceptibility of β -cells to oxidative stress- and ROS-induced damages has been attributed to their inherent poor intrinsic antioxidant defense.^{218, 386–388} This condition, coupled to a progressive 4-hydroxyalkenal-induced inactivation of the 4-hydroxyalkenal neutralizing enzymes FALDH and GST further contribute to β -cell dysfunction.

Hyperglycemia is a major and independent risk factor in the etiology of cardiovascular disease in the metabolic syndrome.^{389,390} The earliest event in this process is endothelial cell dysfunction, which is induced by various stressors, including free radicals and overproduction of 4-hydroxyalkenals. For instance, the expression of adhesion molecules (i.e., ICAM, VCAM) in endothelial cells was altered in the presence of 4-HNE.³⁹¹ Uncoupling of eNOS is induced by 4-HNE-dependent inactivation of THB.³⁹² Moreover, 4-HNE is also involved in the activation of macrophages and foam cells in atherosclerotic blood vessels.³¹⁴ This is attributed to 4-HNE-induced expression of class A scavenger receptors, which transform macrophage to foam cell.³²⁰ Smooth muscle cell proliferation in blood vessels is increased in the presence of 4-HNE.^{393–395} *In vivo* studies show high content of 4-HNE-protein adducts in aortae of streptozotocin (STZ)-diabetic rats.³⁹⁶

6 SUMMARY

Overproduction of free radicals results from an increased availability of glucose and/or FFA to the mitochondria and peroxisomes and following glucose autooxidation, AGE generation, activation of NADPH oxidase, and lipid peroxidation. Detrimental effects of ROS and AGE in the metabolic syndrome include peripheral insulin resistance and impaired β -cell function and viability. In addition,

lipid peroxidation is intensified in the presence of ROS. The peroxidation of PUFAs results in an excessive generation of 4-hydroxyalkenals followed by the formation of covalent adducts with macromolecules, which alter their function. It is important to note that an effective endogenous antioxidant defense and efficient neutralization system of 4-hydroxyalkenal can prevent or delay harmful effects of these agents. Conversely, poor antioxidant defense and ineffective neutralization of ROS and reactive aldehyde species leave cells vulnerable to the combined damaging effects of oxidative stress and peroxidation, as in the case in β -cells in diabetes. Therefore, in addition to the prevention of metabolic disorders by lifestyle and diet changes and pharmacological interventions, an antioxidant therapy is one of the strategies for the treatment of the metabolic syndrome.

1 INTRODUCTION

The use of degenerative chain transfer to control the structure of polymers obtained from radical polymerization was revolutionized in the late 1990s when two research groups independently reported a polymerization using thiocarbonyl thio compounds as chain transfer agents that yielded polymers of controlled molecular weights and narrow molecular weight distributions. The simultaneously reported methods of reversible addition fragmentation chain transfer (RAFT) polymerization by the Commonwealth Scientific and Research Organization (CSIRO)¹ and the macromolecular design via interchange of xanthates (MADIX) by Zard and coworkers in collaboration with Rhodia^{2,a} are arguably the most versatile techniques of living radical polymerization and have become two of the most employed controlled polymerization protocols. Since the two techniques are based on the same mechanism, the term “RAFT” will

be used throughout this article to describe both approaches. Rather than providing a comprehensive review on RAFT chemistry, this article aims at giving an overview of RAFT and highlighting the major strengths as well as limitations of this chemistry. There exists a series of excellent reviews on the topic, and readers wishing to obtain detailed information on all aspects of the RAFT process are directed to those.³ The key strengths of the RAFT process for polymer design are its high tolerance of monomer functionality and reaction conditions as well as its (in-principle) non-rate-retarding nature. A RAFT process—provided the RAFT agent is judiciously chosen—does not induce any rate retardation effects, as the radical concentration during the polymerization is identical to that of a conventional free-radical polymerization process. The only—rather minimal—reduction in radical concentration is caused by the chain-length dependence of the bimolecular termination rate coefficient.⁴ The tolerance of the RAFT process to functional groups

Scheme 1 A selection of RAFT agents.

is extremely high, which permits the synthesis of well-defined polymeric architectures exhibiting almost any functionality, in a wide range of solvents.

The article is divided into several sections, which in turn explore the mechanism of polymerization, the range of polymer molecular weights achievable, the range of monomers in which the polymerization is controlled by RAFT, the various polymeric architectures that can be obtained, the type of end-group functionalities available to RAFT-made polymers, and the process of RAFT polymerization, including emulsion systems.

2 THE MECHANISM OF RAFT POLYMERIZATION

2.1 Mechanism of RAFT Polymerization

RAFT polymerization finds its roots in synthetic organic chemistry based on radical addition–fragmentation processes developed since the 1970s. Among the best known examples of this technique are the Barton–McCombie deoxygenation process with xanthates and later the degenerative transfer of xanthates and related thiocarbonyl thio derivatives in radical addition reactions (see **Xanthates and Related Derivatives as Radical Precursors**).⁵ In the 1980s, several groups started to consider the use of addition–fragmentation chain transfer agents in radical polymerization as a means to control the molecular weight and end functionalities of polymer chains.⁶ The first generations of chain transfer agents all led to irreversible chain transfer

mechanisms and, as a consequence, the polymerization scheme was similar to that of a telomerization reaction. Methacrylate macromonomer RAFT agents (**1**, Scheme 1) appeared in 1995 as the first reversible addition–fragmentation chain transfer agents capable of promoting free-radical polymerizations with living/controlled characteristics.⁷ Later in 1998, a wide variety of thiocarbonyl thio RAFT agents (**2–7**, Scheme 1) including aromatic **2** and aliphatic **5** dithioesters, trithiocarbonates **3**, xanthates **6**, and dithiocarbamates (**4**, **7**) were first reported as quite reactive and efficient control agents in comparison to the macromonomer **1**.^{1,2}

Commonly, RAFT agents are compounds with the general structure **8** (Scheme 2) where the C=X double bond is reactive (in general, X = CH₂ or S). The proper selection of the Z group is crucial in the sense that it must give the RAFT agent **8** (and **10**) an adequate reactivity of the C=X bond for the incoming radical and stability of the intermediate radical **9**. In order to obtain suitable conditions for a RAFT polymerization, the product of the transfer reaction **10** must itself be a good transfer agent. This criterion is fulfilled when A and X are identical. Therefore, RAFT can be seen as a degenerative chain transfer process similar to the one met in radical addition reactions involving thiocarbonyl thio derivatives.

In Scheme 2, R is a radical leaving group that, ideally, should reinitiate polymerization in a fast and quantitative way.

A RAFT polymerization consists of the simple introduction of tenths to several molar percent of a thiocarbonyl thio transfer agent in a conventional free-radical polymerization system. The key feature of the mechanism of RAFT polymerization is a

Scheme 2 Reversible addition fragmentation chain transfer (RAFT) mechanism.

sequence of reversible addition–fragmentation reactions as described in Schemes 2 and 3. The reactions associated with RAFT equilibria shown in Scheme 3 add to those that occur during conventional radical polymerization, namely initiation, propagation, transfer, and termination. At the beginning of the polymerization, polymer chains are initiated (e.g., by an azo initiator) and the addition of a propagating radical ($P_n^\bullet$) to the thiocarbonyl thio compound $RSC(Z)=S$ (**11**) followed by fragmentation of the

intermediate radical **12** generates a polymeric thio-carbonyl thio compound $P_nSC(Z)=S$ **13** and a new radical $R^\bullet$. The formed radical $R^\bullet$ is capable of reacting with the monomer to form a new radical ($P_m^\bullet$). A rapid equilibrium between the active propagating radicals ($P_n^\bullet$ and $P_m^\bullet$) and the dormant thiocarbonyl thio-capped chains **13** provides equal probability for all chains to grow and allows the synthesis of polymers with narrow molecular weight distributions. At the end of the polymerization, the majority of chains

(i) Initiation

(ii) Reversible chain transfer (pre-equilibrium or initialization)

(iii) Reinitiation

(iv) Chain equilibration (main equilibrium)

(v) Termination

Scheme 3 Mechanism of RAFT polymerization showing the initiation, propagation, reversible chain transfer, reinitiation, chain equilibration, and termination steps.

bear the RAFT end group and can be isolated and manipulated as stable products.

As inspection of Scheme 3 indicates, the radical concentration—provided the intermediate RAFT adduct radical is short-lived—is not lower than in a conventional polymerization process. Thus, bimolecular termination events occur and lead to the presence of some nonfunctional material, typically in the range of 5–10%. The control over the molecular weight characteristics is imparted when the targeted molecular weight is significantly lower than that which would be formed under the same conditions but in the absence of the RAFT agent, and is such that the concentration of macromolecules with thiocarbonyl thio-derived ends is much greater than the concentration of chains generated by initiation/termination.

2.2 Kinetics of RAFT Polymerization

Although many RAFT systems show little or no effect of the RAFT agent concentration on the overall rate of polymerization, much past and present debate was reported on the kinetics of the RAFT process, the kinetics of setting of pre- and main equilibria, and what side reactions might add to the complexity of the studied RAFT systems. The RAFT process creates short chains in the early stages of polymerization, which increase in size over the course of the polymerization. As a consequence, the chain-length dependence of the propagation and termination rate coefficients can have a visible impact on the rate of RAFT polymerization compared to a conventional process. Some more marked effects of the addition of a RAFT agent have been reported in the literature, such as

- an inhibition or a period of time during which very little or no polymerization occurs before the polymerization starts;
- rate retardation, that is, a decreased rate of polymerization compared to the same polymerization without a RAFT agent.⁸

Most of the reported cases of inhibition are related to the pre-equilibrium or the so-called initialization step (Scheme 3), where the starting RAFT agent is converted to an oligomeric or polymeric

RAFT agent. For instance, during RAFT polymerization of vinyl acetate and *N*-vinyl pyrrolidone with xanthates, selective initialization occurred in which there was a substantial conversion of the initial RAFT agent into a single unit species before conversion into high molecular weight chains.^{9,10} The effect was attributed to the rate coefficient of the addition of R' to monomer being much slower than that for propagation. Mechanisms for retardation in RAFT polymerization mediated by, in particular, dithiobenzoate RAFT agents have attracted much interest over the last decade. For instance, cumyl dithiobenzoate carries a stabilizing phenyl Z group and a leaving cumyl R group. This RAFT agent has been shown to cause inhibition as well as retardation for a range of monomers. Indeed, in the low-temperature RAFT polymerization of styrene mediated with cumyl dithiobenzoate, the rate of polymerization is initially small—compared to the blank experiment without RAFT agent—and steadily increases.⁹ This could be due to the slow fragmentation of the RAFT adduct radicals formed during the pre-equilibrium, termination of the adduct radicals with themselves or propagating radicals, and slow reinitiation. The mechanism and kinetics of dithiobenzoate-mediated RAFT polymerization were critically evaluated a few years ago.¹¹ Much of the debate surrounding the source of the retardation and inhibition has arisen because of a lack of direct experimental evidence for the lifetime of the RAFT adduct radicals. By necessity, many studies for the determination of individual rate coefficients have taken place within a polymerizing system and require the fitting of data to an assumed kinetic model. This assumption can have a significant influence on the calculated results. Recently, a combination of the spin trapping technique and electron spin resonance (ESR) spectroscopy was employed to obtain the first direct experimental determinations of addition, fragmentation, and self-termination rate coefficients within a model dithiobenzoate system, confirming—at least in this system—a slow fragmentation rate of close 10^{-2} s^{-1} at ambient temperature. These results were found to be in excellent agreement with *ab initio* quantum chemical calculations.¹² Mass spectrometry has also been used to provide evidence for the occurrence of intermediate radical termination during RAFT polymerization of acrylates and styrene with dithiobenzoate RAFT agents. Some studies found traces of three-armed

star polymers¹³ (yet never in sufficient quantities to accord with a high termination rate coefficient), but other studies—both mass spectrometric¹⁴ and via fluorescence marking¹⁵—found none. Perrier and coworkers¹⁶ recently proposed a possible compromise between the slow-fragmentation and intermediate-radical-termination models for retardation in RAFT polymerization with the same RAFT agents. According to the proposed model, intermediate radical termination occurs, but only for initiator-derived or oligomeric species.¹⁷ A complete resolution of all kinetic complexities occurring during the RAFT process is still outstanding.

2.3 Transfer Constants

The rate of consumption of the RAFT agent depends on two transfer coefficients: $C_{tr}(=k_{tr}/k_p)$ and $C_{-tr}(=k_{-tr}/k_i)$, which describe the reactivity of the propagating radical (P_n^*) and the expelled radical (R^*) toward the thiocarbonyl thio moieties, respectively.

The rate coefficient for chain transfer is defined by the product of the rate coefficient for addition to the RAFT agent (k_{add}) and a partition coefficient which represents how the adduct is partitioned between the products and starting materials (1):

$$k_{tr} = k_{add} \frac{k_{\beta}}{k_{\beta} + k_{-add}} \quad (1)$$

In a similar fashion, k_{-tr} is defined for the reverse process (2):

$$k_{-tr} = k_{-\beta} \frac{k_{-add}}{k_{\beta} + k_{-add}} \quad (2)$$

The reverse process cannot be neglected when low- k_p monomers such as styrene or highly reactive RAFT agents (e.g., dithiobenzoates) are used. Moad *et al.* suggested that, when C_{-tr} was ignored and set to zero, the experimental C_{-tr} values should be termed *apparent constants*.¹⁸ They proposed that C_{tr} could be neglected when the independence of C_{tr} on the RAFT agent concentration is established.¹⁸ During polymerization, the propagating radicals P_n^* and P_m^* have similar lengths and reactivities. Therefore, the intermediate radical species **14** is symmetrical and k_{appP} and k_{-addP} are supposed to

be equal. It appears that the rate coefficient for reversible chain transfer (interchain transfer) $k_{tr,PnX}$ is primarily a function of the rate coefficient for addition to the RAFT terminal group (3). The magnitude of interchain transfer depends on the interchain transfer constant $C_{tr,PnX}(=k_{tr,PnX}/k_p)$:

$$k_{tr,PnX} = k_{addP} \frac{k_{-addP}}{k_{-addP} + k_{-addP}} = \frac{k_{addP}}{2} \quad (3)$$

As with any type of living polymerization, the rate of consumption of the RAFT agent and the rate of interchain transfer will dictate the molecular weight profiles and the molecular weight distributions during polymerization.¹⁶

2.4 Molecular Weights and Molecular Weight Distributions

In radical polymerization, the number-average degree of polymerization $\overline{DP}_n$ is defined as the ratio of the monomer concentration consumed at time t and the concentration of chains created at the same time (4). In (4), x is the fractional monomer conversion, $[M]_0$ is the initial monomer concentration, $\Delta[X]_t$ is the concentration of transfer agent consumed at time t , d is the number of chains produced in a radical–radical termination event, and f is the initiator efficiency. As a consequence, the expression of $\overline{M}_n$ is defined by (5) where $M(M)$ is the molar mass of the monomer and $M(RAFT)$ is the molar mass of the RAFT agent.

$$\begin{aligned} \overline{DP}_n &= \frac{[\text{Reacted monomer}]_t}{[\text{Created chains}]_t} \\ &= \frac{x[M]_0}{\Delta[X]_t + df([I_2]_0 - [I_2]_t)} \end{aligned} \quad (4)$$

$$\overline{M}_n = \frac{x[M]_0 M(M)}{\Delta[X]_t + df([I_2]_0 - [I_2]_t)} + M(RAFT) \quad (5)$$

The fraction of living chains (L) (if it is assumed that initiation and termination are the only side reactions) is given by (6).

$$L = \frac{\Delta[X]_t}{\Delta[X]_t + df([I_2]_0 - [I_2]_t)} \quad (6)$$

The reaction conditions are usually selected such that the contribution of initiator-derived chains is negligible (i.e., $L \sim 1$). Under these conditions and in the case of a complete consumption of the RAFT agent early in the reaction (the so-called ideal case), the expressions of $\overline{DP}_n$ and $\overline{M}_n$ are simplified as expressed in (7) and (8), respectively.

$$\overline{DP}_{n,id} = x \frac{[M]_0}{[X]_0} \quad (7)$$

$$\overline{M}_{n,id} = \overline{DP}_{n,id} M(M) + M(RAFT) \quad (8)$$

In nonideal cases, the transfer to the RAFT agent is not fast enough relative to propagation and $\Delta[X]_t$ must replace $[X]_0$ in the mathematical expressions.

A simple integration of the kinetic equation for propagation and transfer reactions gives access to (9) which expresses the effect of C_{tr} of the RAFT agent on the relative evolution of RAFT agent and monomer concentrations during polymerization.

$$\frac{[X]}{[X]_0} = \left(\frac{[M]}{[M]_0} \right)^{C_{tr,X}} \quad (9)$$

From (9), the concentration of chains formed at time t is obtained (10).

$$\begin{aligned} [\text{chains}]_t &= \Delta[X]_t = [X]_0 - [X]_t \\ &= [X]_0 - [X]_0 \left(\frac{[M]}{[M]_0} \right)^{C_{tr,X}} \end{aligned} \quad (10)$$

Equation (10) is simplified as

$$\Delta[X]_t = [X]_0 (1 - (1 - x)^{C_{tr,X}}) \quad (11)$$

Equations (12) and (13) define $\overline{DP}_n$ and $\overline{M}_n$, respectively, for nonideal systems in which the consumption of the RAFT agent is not instantaneous during polymerization:

$$\overline{DP}_{n,non id} = x \frac{[M]_0}{[X]_0} \frac{1}{(1 - (1 - x)^{C_{tr,X}})} \quad (12)$$

$$\overline{M}_{n,non id} = \overline{DP}_{n,non id} M(M) + M(X) \quad (13)$$

Two main cases can be distinguished:

- If $C_{tr} \geq 1$, then $\overline{DP}_n$ equals $[M]_0/[X]_0$ at the end of the polymerization (14). Therefore, the final $\overline{M}_n$ value is controlled under these conditions.

$$\overline{M}_{n,non id} \xrightarrow{x \rightarrow 1} \overline{M}_{n,id} \xrightarrow{x \rightarrow 1} \frac{[M]_0}{[X]_0} M(M) + M(X) \quad (14)$$

- If $C_{tr} < 1$, the experimental $\overline{DP}_n$ values will remain greater than the targeted ones throughout the polymerization, and some unreacted RAFT agent will be present at the end of the polymerization.

The greater the C_{tr} value, the earlier the stage of the polymerization at which the RAFT agent will have fully reacted. A linear growth of $\overline{M}_w$ as a function of monomer conversion is obtained for $C_{tr} > 10$.

In the 1990s, Müller and coworkers predicted the dependence of the degree of polymerization and polydispersity on conversion for polymerizations based on a degenerative transfer mechanism.^{19,20} The theoretical profiles were applied for RAFT polymerizations and were compared with experimental data obtained for methyl methacrylate (MMA) polymerization in the presence of dithiobenzoate esters (Figure 1).^{19,20}

The evolution of polydispersities during polymerization is mainly dictated by the interchain transfer constant $C_{tr,PnX}$. The faster the reversible chain transfer, the narrower the molecular weight distributions, as the chains tend to all have the same probability of growth. Müller *et al.* obtained an expression of $\overline{M}_w$ as a function of C_{tr} (15).

$$\begin{aligned} \overline{M}_{w,non id} &= \frac{[M]_0}{[X]_0} \left(2 + \frac{(2 - x)(1 - C_{tr,X})}{C_{tr,X}} \right) \\ &\times M(M) + M(X) \end{aligned} \quad (15)$$

It was also established that $\overline{M}_w$ and $\overline{M}_w/\overline{M}_n$ values evolve as indicated in (16) and (17) at the end of the polymerization, respectively.

$$\begin{aligned} \overline{M}_{w,non id} &\xrightarrow{x \rightarrow 1} \overline{M}_{w,id} \xrightarrow{x \rightarrow 1} \frac{(C_{tr,X} + 1)}{C_{tr,X}} \\ &\times \frac{[M]_0}{[X]_0} M(M) + M(X) \end{aligned} \quad (16)$$

Figure 1 Predicted dependence of (a) polydispersity and (b) degree of polymerization on conversion in polymerizations involving reversible chain transfer as a function of the chain transfer constant. Predictions are based on the equations proposed by Müller *et al.*^{19,20} with $\alpha = 10^{-7}$, β as indicated, and $\gamma = 605$. Experimental data points are for methyl methacrylate polymerization in the presence of dithiobenzoate esters $\text{Ph}(\text{C}=\text{S})\text{SR}$ (0.0116 M) where $\text{R} = -\text{C}(\text{Me})_2\text{CO}_2\text{Et}$ (○) and $\text{R} = -\text{C}(\text{Me})_2\text{Ph}$ (□). [Reproduced from Ref. 18. © American Chemical Society, 2003.]

$$\begin{aligned} \overline{M}_w/\overline{M}_n &= \frac{\overline{M}_{w,\text{non id}}}{\overline{M}_{n,\text{non id}}} \xrightarrow{x \rightarrow 1} \frac{(C_{\text{tr},X} + 1)}{C_{\text{tr},X}} \\ &= 1 + \frac{1}{C_{\text{tr},X}} = 1 + \frac{1}{C_{\text{tr},\text{PnX}}} \quad (17) \end{aligned}$$

Therefore, a good approximation of $C_{\text{tr},\text{PnX}}$ is obtained by determining the polydispersity index (PDI) value at the end of the polymerization.

2.5 Measurement of Transfer Constants

A number of methods have been reported for determining values of the transfer constants to the RAFT agent. Conventional approaches, such as the Mayo method, are only suitable for low transfer constants and are not appropriate for most of the RAFT agents. An alternative strategy for determining C_{tr} is based on the kinetic model developed by Müller *et al.*^{19,20}

By combining (7) and (12) with (18), it is possible to follow the $\overline{DP}_{n,\text{id}}/\overline{DP}_{n,\text{non id}}$ ratio during polymerization in order to determine C_{tr} .

$$\ln \left(1 - \frac{\overline{DP}_{n,\text{id}}}{\overline{DP}_{n,\text{non id}}} \right) = C_{\text{tr},X} \ln(1 - x) \quad (18)$$

By doing so, C_{tr} is obtained on the basis of one single polymerization experiment. Using this approach, however, the polymerization must be monitored—usually by size-exclusion chromatography (SEC)—at conversions where $\overline{DP}_{n,\text{non id}}$ is still greater than $\overline{DP}_{n,\text{id}}$ (i.e., at conversions where $\overline{M}_{n,\text{exp}} > \overline{M}_{n,\text{th}}$). Therefore, this method is not suitable for high C_{tr} values (>5). The main drawbacks of the two reported techniques are the limitation to relatively low C_{tr} values and the use of experimental $\overline{M}_n$ values usually determined by SEC, which may alter the accuracy of the C_{tr} values. The most used and preferred technique for measuring C_{tr} is based on (9), which is an expression for the evolution of RAFT agent and monomer concentration as a function of C_{tr} . The double-log regression of (9) gives direct access to C_{tr} in one single experiment. This method is known to be more accurate than the others because it is solely based on the accurate measurement of the concentrations of the RAFT agent and monomer over time, for instance by high-performance liquid chromatography.

3 MOLECULAR WEIGHT RANGE

The control over molecular weight, while retaining living chain ends, as well as obtaining a narrow polydispersity, are the key characteristics of living polymerization processes. The most efficient control is typically exerted by anionic polymerization systems, where narrow molecular weight polymers exceeding 10^6 Da are accessible for some

polymer systems (e.g., polystyrene and poly(methyl methacrylate)), as these systems do not suffer from irreversible termination processes. In living radical systems such as RAFT or atom transfer radical polymerization (ATRP) (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**), such high molecular weights are not available with low polydispersities. As seen in the previous section, the reasons for this limitation are the continuous increase of terminated material with increasing monomer-to-polymer conversion as well as a loss in end-group fidelity of the living end groups (e.g., elimination (ATRP) or oxidation and hydrolysis (RAFT) reactions). In addition, the most important factor restricting high molecular weights is the limit to which the concentration of the controlling agent can be lowered in relation to the employed radical initiator concentration. An efficient RAFT process relies on the high rate of reaction between the propagating chains and the thiocarbonyl thio moiety, which exceeds the rate of termination of two macroradicals ideally by a factor larger than 10^4 . A strong reduction in the RAFT agent concentration thus leads to a decrease of the above ratio, and typically molecular weights exceeding 200 kDa are not accessible without a loss of control, that is, a significant broadening of the molecular weight distribution as well as the occurrence of hybrid behavior. Hybrid behavior is a phenomenon that occurs when the addition rate of the propagating radicals with the initial RAFT agent ($R_{\text{add}} = k_{\text{add}} [\text{RAFT}] [P_n]$) is significantly lower than that of propagation ($R_p = k_p [P_n] [M]$). An inspection of the respective rate law expressions indicates that it can be caused by too low an addition rate coefficient, k_{add} , (e.g., when attempting to mediate a styrene polymerization with a xanthate) or too low a concentration of the RAFT agent. Its macroscopic manifestation is an initial sharp increase in the molecular weight at very low conversion, followed by linear macromolecular growth with conversion, which asymptotically approaches the theoretical limit. Inspection of the respective rate equations thus indicates that attempts to generate high molecular weight polymers via the RAFT process with a concomitant suppression of hybrid behavior should be carried out at high monomer concentrations with RAFT agents that enable the rapid addition of macroradicals, such as dithiobenzoates.

To address the problem of preparing high molecular weight polymers (and concomitantly improving the block copolymer formation process) via the RAFT process, Matyjaszewski and colleagues recently introduced a methodology that combines RAFT chemistry with the ATRP process, allowing the generation of well-defined, high molecular weight material.²¹ The process takes advantage of the fact that dithioesters can act as pseudo-halogens under conditions that are normally employed during an ATRP process. The key idea here is that, in both ATRP and RAFT, termination reactions occur (in RAFT even more than in ATRP, due to the nonreduced overall propagating radical concentration), yet there is no steady radical influx into a combined RAFT/ATRP system, preventing a tailing of the molecular weight distribution. The general working principle of concurrent RAFT/ATRP is depicted in Scheme 4. The authors were able to demonstrate that the system functions well for styrene and MMAs, when cumyldithiobenzoate is employed as the RAFT agent. For example, poly(methyl methacrylates) could be prepared with a molecular weight of up to 500 kDa and a polydispersity of approximately 1.3. Thus, the process represents an efficient avenue for the preparation of high molecular weight polymers via an adapted RAFT process. An alternative—and also relatively facile—method has recently been suggested by Gerstel and Barner-Kowollik, who employed a diradical initiating species derived from Bergman cyclization to achieve high molecular weight RAFT generated polymers with relatively narrow polydispersities (up to 400 kDa).²²

Scheme 4 Proposed reaction mechanism for concurrent RAFT/ATRP. Note that no additional thermal initiation source is required. Concurrent RAFT/ATRP allows the generation of high molecular weight polymers ($M_n > 500$ kDa) with relatively low PDI (< 1.3). [Adapted from Ref. 21. © American Chemical Society, 2008.]

While it is often desired to prepare macromolecules with low polydispersity and high molecular weights, it is also sometimes a requirement to generate well-defined polymeric materials in the oligomeric range (e.g., for the provision of modular macromolecular building blocks for the preparation of brush-like structures). The RAFT process is especially suited for generating well-defined, high end-group fidelity, low molecular weight material, as long as the RAFT agent/monomer combination is chosen such that hybrid effects (see above) do not prevent the generation of very low molecular weights (i.e., the pre-equilibrium is passed rapidly). From the kinetic equations governing the RAFT process, it is immediately evident that the (instantaneous) degree of polymerization versus monomer-to-polymer conversion correlation can never pass through the origin and only through degree of polymerization = 1. If the degree of polymerization versus conversion correlation were to pass through the origin, the ratio of the propagation rate coefficient, k_p , and the addition rate coefficient of the macro- and primary radicals to the initial RAFT agent, k_{add} , had to be zero, implying that k_{add} must be infinity or k_p zero—two conditions which cannot be fulfilled.²³ Very low PDI polymers in the oligomer range (number average molecular weight between 500 and 5000 Da) can be obtained when the radical concentration is kept low over the duration of the polymerization and a high k_{add} RAFT agent and relatively low k_p monomer are employed. Although such a scenario sounds somewhat exotic, it is easy to implement, for example, in the systems styrene/cumyldithiobenzoate (CDB) or cyanoisopropylthiobenzoate (CPDB) and—at temperatures not exceeding ambient to reduce k_p as much as possible—in acrylate/CDB or CPDB systems. The degree of low molecular weight control with low polydispersities is an advantage of RAFT over ATRP and other processes, where (due to the persistent radical effect) control tends to increase only with increasing conversion and thus concomitantly increasing molecular weights.

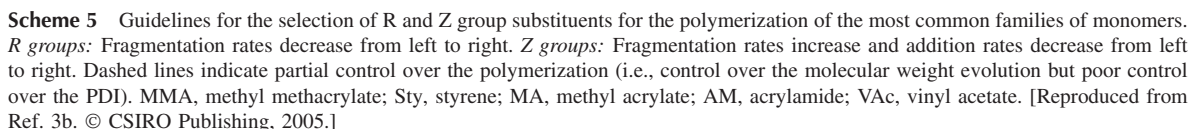

4 MONOMER RANGE

One of the key strengths of the RAFT process is its high tolerance of functional groups. RAFT polymerization has been shown to effectively mediate

the polymerizations of almost all the monomers that can be polymerized via conventional free-radical polymerization, in the bulk, organic, and aqueous solvents. Often, the control over polymerization depends on the careful choice of the RAFT agent. Scheme 5 gives general guidelines for the choice of appropriate substituents of a RAFT agent, depending on the monomer considered.

The polymerization of styrene is very well controlled when mediated by dithioesters, trithiocarbonates, and dithiocarbamates (where the nitrogen lone pair does not strongly conjugate with the thiocarbonyl bond), with typical PDIs ranging from 1.03 to 1.25, while poor control is obtained from xanthates and alkyl dithiocarbamates (with PDIs ranging from 1.5 to 2.0). Preventing the conjugation of the lone pair of the Z group heteroatom with the thiocarbonyl thio group can increase the reactivity toward radical addition of the C=S bond of these RAFT agents. This is achieved by the inclusion of electron-withdrawing groups attached to the alkoxy Z group or, in the case of dithiocarbamates, where the nitrogen lone pair is conjugated into an aromatic ring system. In addition, the intermediate radical is less destabilized by the lone pair, which reduces the rate of fragmentation, thus improving the RAFT agents' ability to mediate the polymerization. Unfortunately, the limited number of functionalized styrene derivatives restricts the access to functional materials.

Acrylates and acrylamides are among the most versatile monomers with respect to the classes of RAFT agents that can control their polymerization. Acryloyl propagating radicals are relatively reactive because they are secondary radicals and therefore have a low steric bulk. Furthermore, acrylates do not possess any strong radical stabilizing groups. The relative instability of acryloyl propagating radicals means that a wide range of R groups can be used since many are more stable and thus better leaving groups than these radicals. Additionally, the adduct radical that is formed by addition of an acryloyl radical is relatively stable, and therefore a Z group that produces a lower stabilizing effect, such as in dithioacetates, trithiocarbonates, and appropriately substituted dithiocarbamates, is necessary to promote fragmentation of the adduct radical. Dithiobenzoate-mediated acrylate polymerizations, on the other hand, often exhibit an induction and rate retardation phenomenon, the origin of which has been discussed extensively in the literature.²⁴

Methacrylates and methacrylamides are among the more challenging families of monomers to polymerize via the RAFT process, because of their bulky tertiary propagating radicals. In order for a methacryloyl propagating radical to efficiently add to the thiocarbonyl bond of the mediating chain transfer agent (CTA), the reactivity of the thiocarbonyl bond toward radical addition must be high. Furthermore, the adduct radical formed by addition of the propagating radical to the RAFT agent must be sufficiently stabilized so that fragmentation does not occur too rapidly. For these reasons, xanthates offer very little control over the polymerization of methacrylates. The thiocarbonyl groups of aliphatic dithioesters, trithiocarbonates, and dithiocarbamates (with aromatic Z groups) are more reactive than those of xanthates. In addition, the Z groups of these

RAFT agents do not cause as much destabilization of the adduct radical as xanthates, and therefore they exhibit reduced rates of fragmentation, resulting in increased control over the polymerization. However, the most appropriate Z groups for the polymerization of methacrylates are phenyl (e.g., dithiobenzoates), as the thiocarbonyl group is relatively reactive and the adduct radical is most stabilized by these RAFT agents. The choice of R group on the CTA is particularly important in methacrylate polymerizations because, as with all successful RAFT polymerizations, the R group must be a better leaving group than the propagating radical. The most successful R groups for methacrylate polymerization are both bulky and capable of stabilizing the radical. Cyanoisopropyl and cumyl R groups tend to be the most effective as they possess steric bulk and functional groups (-CN and -Ph, respectively) that are able to stabilize the R group-derived radical. Interestingly, there are very few RAFT agents with an R substituent generating a secondary radical that gives good control over methacrylic polymers.²⁵ The families of (meth)acrylate and (meth)acrylamide monomers are of great interest to

Figure 2 Examples of functional 4-vinyl-1,2,3-triazole monomers. [Reprinted with permission from Ref. 27a. Copyright 2006 American Chemical Society.]

polymer chemists, since they offer a wide range of functionalities. Indeed, in addition to the hundreds of monomers commercially available, one can transform any molecule bearing a hydroxyl or amine functional group into the corresponding monomer, by simple esterification with (meth)acryloyl chloride. Such a modular approach to monomer design enables the introduction of a wide array of functionalities into monomeric building blocks.

Vinyl acetate (VAc) is a relatively low reactive monomer (i.e. generating a highly reactive radical) owing to poor stabilization of the propagating radical and low steric bulk. Since the lack of stability of VAc propagating radicals makes it a poor leaving group in the RAFT adduct intermediate radical, only RAFT agents such as xanthates and *N,N*-dialkyl dithiocarbamates, with a Z group that destabilizes the intermediate radicals, can effectively mediate the RAFT polymerization of VAc. The same is true for other monomers of relatively high reactivity, such as vinyl pyrrolidone. Interestingly, RAFT is, to date, the best technique to control the polymerization of vinyl acetate and its derivatives.

Beyond these common families of monomers, a variety of other monomer classes have been successfully polymerized by RAFT, including, for instance, isoprene, 2- and 4-vinylpyridine, acrylonitrile, and vinyl sulfonate esters. Mori *et al.* showed that xanthates could efficiently control the polymerization of this latter family of monomers to yield sulfonated block copolymers.²⁶

An elegant approach to increase the range of functional monomers was introduced by Hawker

and coworkers, who presented the RAFT polymerization of 4-vinyl-1,2,3-triazole monomers. These triazole derivatives are easily synthesized via copper-catalyzed [1 + 3] dipolar cycloaddition and present an entirely new class of functional monomers (Figure 2).²⁷

There may be occasions when the desired functionality cannot be introduced via the monomer prior to polymerization because of incompatibility with the RAFT agent (see below) or incompatibility with the reaction conditions. In this case, it is common to exploit high-yielding organic addition reactions (“click” chemistry, see section below *Modular Design* and **Radical Thiol–X Click Chemistry**) to add the targeted functionality to the polymer after polymerization, in a modular approach. To this effect, a number of monomers have been designed that allow the addition of functional groups postpolymerization. The most common examples of this convergent synthetic strategy employ activated esters such as *N*-(meth)acryloxysuccinimide²⁸ and pentafluorophenylmethacrylate,²⁹ as well as aldehyde derivatives such as 4-vinylbenzaldehyde,³⁰ methyl vinyl ketone, and phenyl vinyl ketone³¹ (for addition of amines). It is also interesting to note that thiol exchange reactions have been used, by polymerizing monomers such as pyridyldisulfide ethylmethacrylate via RAFT to create a polymeric scaffold, which can be functionalized by the addition of a variety of thiols.³²

The mechanism of RAFT polymerization relies on the activation of the monomer double bond

to enable efficient fragmentation from the intermediate radical, which gives control over the molecular weight of the resulting polymer. It follows that vinyl monomers, for which the double bond is not activated, are still challenging to polymerize efficiently via RAFT. In certain cases, a more reactive RAFT agent, such as one from the families of xanthates and *N,N*-dialkyl dithiocarbamates, is more adapted to such monomers. For instance, the polymerization of diallyldimethyl ammonium chloride (DADMAC) was shown to be controlled by xanthates, to yield polymers of well-controlled molecular weights.³³ Attempts have been made to control the polymerization of 1-alkenes³⁴ and allyl butyl ethers³⁵ yet, to date, only copolymerization with active monomers (acrylates and acrylamides) have led to relatively good control with a low amount of the nonactivated alkene present in the final product. The controlled polymerization of ethylene, one of the most widespread monomers in free-radical polymerization, still remains a challenge.³⁶

A noteworthy drawback of RAFT polymerization in terms of functionality is the reactivity of the thiocarbonyl thio group toward amines. Primary and—under appropriate conditions—secondary amines react with the thiocarbonyl thio group to form carbamates, which leads to the deactivation of the chain transfer agent. Therefore, it is difficult to control the RAFT polymerization of amine-containing monomers. Of course, a simple route to circumvent this problem is to use the modular approach described below, where the amine functionality is added to the polymer backbone postpolymerization.

5 POLYMERIC ARCHITECTURES

With ever-increasing application-based demands on polymeric materials in the fields of biotechnology and nanotechnology, gaining fine control over macromolecular structure to produce precisely engineered materials is currently a key issue for polymer scientists to address. In order to produce polymers for such specific applications, it is necessary to have control over not only the molecular weight and incorporated functionalities but also, and perhaps of more importance, the architectural design—that is the three-dimensional connectivity between the monomer units—of the polymer. When carefully

designed, RAFT polymerization opens the door to a wide range of polymer architectures—thus the ability to subtly tune polymer properties—via a number of variable approaches.

Similar to other living radical polymerization techniques, block copolymers, star and comb polymers, as well as graft polymers are all accessible by attaching the controlling RAFT agent to a (multi)functional core linking moiety (as shown in Scheme 6). In addition, more complex multiblock systems based on these architectures can be obtained by chain extension of the RAFT moiety capped block.

Unique to the RAFT process are the possible modes of attaching the RAFT group covalently to the (multi)functional moiety.³⁷ The nature of the controlling agent allows two distinct approaches, the R- and Z-group approaches, to the design of complex architectures, of which only one is easily available in, for example, ATRP (see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**)³⁸ and nitroxide mediated polymerization (NMP, see **Nitroxide-Mediated Polymerization and its Applications**).³⁹ While all the aforementioned techniques focus on a starting with multifunctional RAFT agents and divergent syntheses, the presence of the thiocarbonyl thio group postpolymerization also allows for an arm-first (or convergent) synthesis of all these structures, where this end group can be utilized in conjugation reactions.

The critical issue in all these approaches is the ability to maintain the fidelity of the thiocarbonyl thio end group. Undesired bimolecular termination reactions, high initiator concentrations, or chain transfer to monomer or solvent can reduce the amount of RAFT end-capped polymer chains. It is therefore paramount that, before attempting to generate complex architectures, optimization and fine-tuning of polymerization variables (such as those discussed in the previous sections) are carried out on simpler systems.

In the following sections, we will highlight the example of block copolymer synthesis in much greater detail to demonstrate the variety of parameters and synthetic techniques, from both divergent and convergent pathways, available in RAFT systems. We will also discuss some of the limitations of these systems and strategies that can be employed to avoid these situations. It should

Scheme 6 Selection of complex polymer architecture formation pathways prepared via RAFT polymerization. [Adapted from Ref. 37. © Wiley-VCH Verlag GmbH & Co. KGaA, 2008.]

be noted that all the benefits and shortcomings discussed with regard to the block copolymer synthesis are also applicable to the synthesis of some of the more exotic polymer architectures. For additional specific examples of RAFT systems being employed for the formation of higher order architectures, the reader is directed to Refs 3, 37, 40 and 41.

5.1 The Example of Block Copolymers: Divergent Synthesis

Block copolymers are arguably the most important polymer class that can be prepared via living radical polymerization processes, including RAFT chemistry. A wide variety of block copolymers have indeed been accessed via the RAFT

process—including amphiphilic ones—mostly via a sequential polymers design, implying that a first block is prepared, which is subsequently (after isolation) redissolved and chain-extended with a second monomer. In theory, this process can be repeated several times, thus in principle providing access to narrow-polydispersity multiblock copolymer structures. In practice, the generation of block copolymers of high purity requires a careful choice of the RAFT agent as well as a compatible solvent for both blocks. As the RAFT process relies on a radical addition fragmentation equilibrium, not all combinations of monomers may be employed to generate the respective blocks. The more disparate the reactivities of the associated propagating radicals, the more problematic it is for the formation of the respective block structure. For example, it is—with classical RAFT agents—impossible to generate block copolymers of polystyrene and poly(vinyl acetate), as there exists no common RAFT agent. The polymerization of styrene can be mediated by a wide array of RAFT agents (see above), while vinyl acetate may only be mediated by xanthates and dialkyl dithiocarbamates, which cannot induce control over styrene polymerizations. Two principal solutions to this problem exist. The first will be addressed in detail below in the section on *Modular Design*, where the two blocks are independently generated and subsequently ligated via an efficient conjugation strategy. The second approach entails the design of a RAFT agent, which can offer universal control over any monomer, irrespective of the reactivity of the propagating radical center.

Before we turn our attention to universal RAFT agents, the section below will explore some of the limitations as well as strengths of block copolymer generation. Prior to exploring some detailed chemistries, a general word of caution: It has been common practice in the literature to demonstrate the efficiency of chain extension via a plot showing the evolution of the molecular weight distribution as well as the initial block in a diagram where all distributions are normalized with regard to their peak maximum. Such a representation can be misleading in judging the quality of the chain extension, as it overemphasizes the M_p of each distribution. With such a representation, it cannot be adequately judged what quantity of material is not chain-extended (“left behind”). It is thus much more preferable to scale the

extension molecular weight distributions relative to the achieved monomer-to-polymer conversion of the second monomer. A detailed description of the two forms of data presentation can be found in Ref. 42.

Within the literature, a wealth of functional examples with regard to block chain extension by sequential monomer addition can be found. As with homopolymerizations mediated via the RAFT process, block extensions can suffer from loss of control when attempts to reach high molecular weight blocks are made. However, access to moderate molecular weight blocks (~50–70 kDa) with good reaction control is readily achievable. Rizzardo, Moad, and coworkers demonstrated two examples with the synthesis of poly(methyl methacrylate)-*b*-styrene and poly(dimethylaminoethyl methacrylate)-*b*-styrene.⁴³ Both systems had an overall molecular weight of greater than 100 kDa while the polydispersity was kept below 1.3. Because of the excellent functional group tolerance of RAFT polymerizations, access to hydrophobic–hydrophobic (e.g., poly(methyl methacrylate)-*b*-styrene), hydrophilic–hydrophilic (e.g., poly(*N,N*-dimethylacrylamide)-*b*-(*N,N*-dimethylvinylbenzyl-ammonium chloride)⁴⁴) and hydrophobic–hydrophilic (e.g., poly(octadecyl acrylate)-*b*-(*N*-vinyl pyrrolidone)⁴⁵) diblock systems are possible.

The formation of block copolymers by sequential monomer addition is in no way limited to only AB diblocks. There are a number of examples of higher order ABA and ABC triblocks formed using the diblock copolymer as a macro-RAFT agent. Zhao, Perrier, and coworkers have demonstrated this to the greatest extent, producing a series of ABCD tetrablock copolymers, all of which, as shown by the representative example in Figure 3, displayed little to no loss in control of the polymerizations, even after the addition of the fourth block (e.g., polystyrene-*b*-(*N*-acrylomorpholine)-*b*-(*N*-isopropylacrylamide)-*b*-(methyl acrylate), $\overline{M}_n = 23\,200$ Da, PDI = 1.19).⁴⁶ Using similar chain-extension conditions but switching from a mono- to a bis-RAFT agent allows facile access to symmetrical triblock copolymers. Moad and coworkers applied this type of bis-RAFT agent to the synthesis of poly(styrene-*co*-acrylonitrile)-*b*-(butyl acrylate)-*b*-(styrene-*co*-acrylonitrile) copolymers for applications as thermoplastic elastomers.⁴⁷ This again demonstrates that moderately high molecular

Figure 3 SEC traces of polystyrene, polystyrene-*b*-(*N*-acrylomorpholine) (PSt-*b*-PNAM), polystyrene-*b*-(*N*-acrylomorpholine)-*b*-(*N*-isopropylacrylamide) (PSt-*b*-PNAM-*b*-PNIPAM), and polystyrene-*b*-(*N*-acrylomorpholine)-*b*-(*N*-isopropylacrylamide)-*b*-(methyl acrylate) (PSt-*b*-PNAM-*b*-PNIPAM-*b*-PMA) prepared via subsequent chain extensions via the RAFT process employing *S*-methoxy-carbonylphenylmethyl *S*-trimethoxysilylpropyltrithiocarbonate (MPTT). [Reproduced with permission from Ref. 46. Copyright 2009 American Chemical Society.]

weight initial (poly(butyl acrylate), $\overline{M}_n = 77\,000$ Da) and chain-extension blocks (polystyrene block ~ 50 kDa) can be synthesized using this methodology, without having to sacrifice reaction control (PDI = 1.2).

While not exclusively related to block copolymer synthesis, the formation of many of the more complex architectures available through RAFT polymerization—including those based on a single monomer—share the characteristics and caveats of linear block copolymer formation. One technique to obtain such structures (akin to the triblock synthesis mentioned before) is the use of higher level multifunctional RAFT agents. A synthetic approach with a multifunctional core or a RAFT agent functionalized polymer backbone allows the synthesis of polymer star or graft to polymers, respectively. Whether the RAFT agents are linked via their Z- or R-groups to the core/backbone of the molecule governs whether the thiocarbonyl thio moiety remains at the center or is found at the periphery of the arms' chains. The choice of Z- versus R-group approach has consequences when considering the synthesis of diblock copolymer variations of such molecules, as the choice of starting agent will dictate which block ultimately finishes nearer the core. In addition, the

choice of Z- versus R-group has significant consequences with regard to the uniformity of the generated polymeric materials. In the R-group approach, multifunctional RAFT agents can lead to multimodal molecular weight distributions, owing to the fact that the core is a radical-carrying entity, allowing star-star coupling to occur. Z-group approaches can lead to limited molecular weights, potentially caused by steric crowding around the multifunctional core to which the thiocarbonyl thio moiety is tethered. As it is not the aim of the current article to explore in depth complex macromolecular architecture formation via the RAFT process, the interested reader is referred to the existing reviews and studies on this topic.^{42,48} Alternatively, graft-type polymers can be formed using a grafting-through technique employing the polymerization of macromonomers (or a combination of monomer and macromonomer), which have reactive vinyl end groups, in the presence of a suitable RAFT agent. Access to highly branched systems is further possible by the addition of a controlled amount of multifunctional vinyl compound.⁴⁹

When planning the synthesis of block copolymers, it should be noted that the leaving group of the newly formed macro-RAFT agent is the previously polymerized chain. It is therefore very

important to consider the order in which the blocks are polymerized. If the monomers vary markedly in reactivity (e.g., styrenic/acrylic or methacrylic), this can impact on the preferential fragmentation of transient macro-RAFT radicals in the direction of the most stable radical during the chain transfer step. Such problems are illustrated in the polymerization of MMA and styrene.¹⁸ When MMA is polymerized in the presence of cumyldithiobenzoate ($\bar{M}_n = 14700$ Da, PDI = 1.21) followed by block extension with styrene to approximately double the molecular weight, complete conversion to poly(methyl methacrylate)-*b*-styrene is observed ($\bar{M}_n = 35000$ Da, PDI = 1.24). Taking the same experimental conditions but reversing the block order gives a very different result. Examination of the final mixture shows the presence of unchanged polystyrene macro-RAFT agent ($\bar{M}_n = 20000$ Da, PDI = 1.15) as well as uncontrolled poly(methyl methacrylate) homopolymer ($\bar{M}_n = 290000$ Da, PDI = 2.63), similar to that obtained from a conventional radical polymerization. While this example illustrates the point using two monomers of clearly differing reactivity, in some cases the differences are not as obvious. When examining the example shown in Scheme 7, a low level of blocking efficiency is observed when a poly(*N*-acryloyloxysuccinimide-*co*-*N,N*-dimethylacrylamide) (P(DMA-*co*-NAS)) macro-RAFT agent is used to polymerize *N*-isopropylacrylamide (NIPAM). When the blocks are reversed however, the formation of well-defined copolymers is achieved.⁵⁰ As mentioned previously, sometimes even when taking into account block order, some monomer combinations cannot be polymerized under controlled conditions using classical RAFT agents. While there are dual polymerizations approaches (e.g., RAFT-ATRP) and alternative ligation techniques that allow such copolymers to be synthesized, there is also a substantial focus on the synthesis of new-generation universal RAFT agents to circumvent the difficulties associated with block formation from monomers of disparate reactivity.

The first design of a universal RAFT agent was suggested by Coote, Barner-Kowollik, and colleagues. These authors noted—via quantum chemical calculations—that when $Z = F$, the fluorine group should increase the reactivity of the C=S double bond toward radical attack, while ensuring that the generated adduct RAFT radicals are

rapidly fragmenting. At first sight, such a situation seems impossible to achieve, as the driving force of the addition reaction of the attacking radical is directly correlated with the stability of the generated adduct. As a consequence, a highly reactive radical will add to thiocarbonyl thio compounds with a stabilizing Z-group (such as phenyl) and the resulting intermediate species will only sluggishly fragment. When fluorine is employed as a Z-group, a homoanomeric effect allows a highly destabilized intermediate radical while maintaining the C=S bond reactivity over a wide attacking radical reactivity range.⁵¹ It goes without saying that the leaving group must suit the nature of the propagating radical. To date, only F-RAFT agents featuring isopropyl and benzyl R-groups have been prepared (see Scheme 8) and employed to mediate styrene, acrylate, and ethylene³⁶ polymerizations. Variants featuring more suitable R-groups (such as cyanoisopropyl) are synthetically difficult to access. Only the provision of such F-RAFT agents may make them suitable to mediate a wide range of disparate reactivity monomers and thus the potential applicability of F-RAFT has yet to be demonstrated.

Synthetically more accessible, and thus more widely employable, is a class of switchable RAFT agents recently introduced by Rizzardo, Moad, Thang, and colleagues.⁵² These authors employ a dithiocarbamate compound that can be reversibly protonated, thus changing the stability of the electronic configuration of the C=S double bond (see Scheme 8). Employed for this purpose are dithiocarbamates carrying a pyridyl ring attached to the carbamate nitrogen. When the pyridyl nitrogen is protonated, the electronic properties of the carbamate nitrogen are changed. In its protonated state, the C=S bond length is decreased, making the RAFT agent suitable to control the polymerization of (meth)acrylate-type monomers as well as styrene. In its unprotonated state, these RAFT agents are suitable for mediating the polymerization of monomers, forming reactive propagating radicals, such as vinyl acetate or *N*-vinyl pyrrolidone. The ability to use such a RAFT agent for the preparation of block copolymers from monomers with disparate reactivities was recently shown. In this example, styrene is polymerized first with the protonated RAFT agent. The obtained macro-RAFT agent is subsequently deprotonated with sodium carbonate and the polymer then undergoes block extension with vinyl acetate.⁵³ The process appears to work

well, although more in-depth studies are required to assess its full scope.

5.2 The Example of Block Copolymers: Convergent Synthesis

While sequential polymer design strategies have dominated living (radical) polymerization protocols, recently a paradigm shift⁵⁴ in how complex macromolecular architectures are constructed has occurred. By using high-yielding organic addition reactions that are orthogonal to the polymerization, polymer chemists can now design complex functional macromolecular architectures by following

a modular approach. In this convergent synthesis route, the polymer is built and subsequently reacted postpolymerization, to form the desired product in high yields. This approach has been employed to react either the end of the polymeric chains or the backbone of the polymer (by introducing the required functionality via the monomer). We have described above the use of functional monomers and will focus on the end-group chemistry in the current section. Macromolecules are either equipped with end groups or already carry suitable end groups as a result of the control process, which can be employed in macromolecular ligation, preferably under mild reaction conditions and without the use of toxic catalysts. One of the most employed conjugation protocols is the

copper catalyst 1,3-dipolar Huisgen cycloaddition between an azide and an acetylene. However, a host of other protocols—some of which specifically exploit RAFT chemistry, such as the RAFT–hetero Diels–Alder (RAFT–HDA) approach—are available. These are summarized under the term “click” chemistry and have been thoroughly reviewed.⁵⁵ Here, we focus on those conjugation protocols that have been employed in the context of the RAFT process to generate complex macromolecular designs.

The combination of RAFT chemistry with orthogonal polymer–polymer conjugation can be a convenient avenue to block copolymer structures in cases where no suitable RAFT agent for both monomers is available or where both homopolymers need to be analyzed and prepared separately. The advantage of the modular approach is thus that the individual building blocks can be characterized in depth before they are ligated. One of the earliest examples of conjoining RAFT homopolymers is the preparation of vinyl acetate/styrene block copolymers.⁵⁶ In this approach, two individual RAFT agents are prepared—one capable of mediating the polymerization of styrene (i.e., a dithiobenzoate) and carrying an (protected) acetylene group, the other capable of mediating the polymerization of vinyl acetate and equipped with an azide moiety. Both homopolymers are prepared separately with the desired molecular weight and subsequently conjugated via standard conditions of copper catalyzed [2 + 3] dipolar cycloadditions. Similar azide functional RAFT agents (in the form of trithiocarbonates and dithiobenzoates) have been prepared by Sumerlin and colleagues and were employed to mediate the polymerization of styrene and *N,N*-dimethyl acrylamide.⁵⁷ Subsequently, the resulting azide functional polymers have been reacted with a range of alkyne functional species to generate well-defined telechelic materials. Without doubt, the obtained azide-functional trithiocarbonate-based macro-RAFT agents can also be employed for conjugation reactions with polymers prepared via acetylene-capped RAFT polymers. Figure 4 provides examples of azide and alkyne functional RAFT agents as well as the general synthetic ligation strategy alongside an example conjugation of poly(vinyl acetate) and polystyrene. While the above approach often works very well, it has limitations. One, which was foreseen by the authors of Ref. 56, is the potential reaction

of propagating or primary radicals with acetylene moieties during the RAFT polymerization process. To minimize these interactions, the acetylene group can be protected with a trimethylsilyl group, which can be readily removed via hydrolysis, after the polymerization process. A similar protective approach can also be taken when monomers containing acetylene units are polymerized.⁵⁸ In the case of acetylene-functionalized RAFT agents, protection can be avoided, but temperatures must remain low, and monomer conversions must be limited to 80% or below.⁵⁹

In addition to complications with the acetylene group, the most significant of the potential limitations is the observation made by Perrier and coworkers that azides, when, for example, attached to a RAFT agent, can undergo 1,3-cycloadditions with monomeric vinyl bonds, in a similar fashion as they do during reaction with acetylene (Scheme 9).⁶⁰ This side reaction affects more significantly acrylates and acrylamides, since it depends on the electron-withdrawing properties of the vinyl bond substituent. Steric hindrance of the double bond, for instance in the case of methacrylates, limits the reaction. Monomers such as styrene, with delocalization of the double bond to the benzene ring, are less reactive. For instance, test reactions of methyl acrylate, dimethyl acrylamide, *N*-isopropyl acrylamide, methyl methacrylate, and styrene with benzyl azide at 60 °C (with a molar ratio monomer/azide of 4 : 1) have shown that conversions of 95.2, 89.4, 79.3, and 27.2%, respectively, are obtained within 20 h.⁶⁰ In order to limit these side reactions during polymerization, the reaction time should be kept short (e.g., under 5 h at 60 °C) and/or the temperature should be kept low.

While equipping RAFT agents with groups that allow modular conjugation chemistry can be a route to complex polymer architectures, an alternative possibility is to employ the dithioester functionality itself as one side of a linkage reaction. Such a concept was realized in the form of the RAFT–HDA concept, where highly electron-deficient dithioesters are employed to mediate the polymerization and are subsequently used in HDA reactions with suitable dienes. If the diene is judiciously chosen, very rapid reaction (minutes) to quantitative polymer–polymer conjugation can be achieved at ambient temperatures.⁶¹ A typical set of HDA-capable RAFT agents is depicted in Scheme 10. Best conjugation results

Figure 4 (a) Typical azide and acetylene functional RAFT agents (1) to (4) (according to Refs 54, 55) as well as a typical conjugation product (5). Note that acetylene functional RAFT agents are often employed with protected acetylene as in (2), since the carbon–carbon triple bond can react with radicals during the polymerization processes. (b) The example (taken from Ref. 56) demonstrates the coupling of two individual molecular weight distributions of poly(vinyl acetate) and polystyrene to form a block copolymer via [1 + 3] dipolar cycloaddition. The number average molecular weights of the constituting blocks is close to 7500 and 6800 Da, whereas the conjugate features a number average molecular weight of 15 200 Da.

and shortest reaction times are achieved when cyclopentadiene-capped polymers are employed as dienes. Preparing block copolymers using these systems can result in products with molecular weights over 100 kDa.⁶² If the dithioester is extremely electron deficient (as in sulfonyldithioformates), the reactivity of the C=S diene can become so high that it will react with monomers such as styrene or acrylates in Diels–Alder reactions, even breaking the aromaticity of the phenyl ring in styrene.⁶³ In such cases, only monomers that display a high degree of steric bulk (such as isobornyl

acrylate) can be polymerized. However, extremely electron-deficient dithioesters can find applications in surface conjugation approaches, where surfaces covered with styryl groups can be readily reacted with sulfonyldithioformate-capped poly(isobornyl acrylates) in an efficient fashion.⁶⁴ Conventional RAFT agents such as trithiocarbonates, dithioacetates, and dithioesters, as well as xanthates or carbamates without a Diels–Alder activating Z-group, will not—even with the most reactive dienes such as cyclopentadiene—function well in HDA reactions.

Scheme 9 Proposed mechanistic pathway for the 1,3-cycloaddition of an azide group (attached to a RAFT agent) to the vinyl bond of *N*-isopropylacrylamide. [Reprinted with permission from Ref. 60. Copyright 2008 American Chemical Society.]

Scheme 10 RAFT agents capable of undergoing RAFT–hetero Diels–Alder reactions in polymer–polymer conjugations. Note that the C=S double bond in sulfonyldithioformates (**3a,3b**) is of such high dienophilicity that it will readily react with diene structures present in many monomers (C=C–C=C or C=C–C=O), unless these feature a high degree of steric bulk preventing the [2 + 4] cycloaddition.

The RAFT–HDA concept relies strongly on the provision of diene-capped polymers, specifically those carrying the reactive cyclopentadienyl (Cp) group. Recently, a mild ambient temperature approach toward Cp-capped polymers was introduced by one of the authors. Employing nickelocene allowed the transformation of virtually

all ATRP-prepared polymers into Cp-capped entities in a quantitative fashion.⁶⁵ The RAFT–HDA approach is not only suited for the preparation of block copolymers (or more complex structures)⁶⁶ but stands to be exploited as a tool for the preparation of telechelic polymers by reacting the electron-withdrawing polymer termini with

small molecule dienes.⁶⁷ It goes without saying the RAFT–HDA chemistry also has limitations, such as the (at present) limited choice of RAFT agents that may be employed (see Scheme 10).

A further ligation protocol employs indirectly the thiocarbonyl thio-reactive group, which, after having controlled the growth of polymeric chains, can be transformed into a thiol and utilized as a handle for functionalization of the resulting polymer chain ends. The thiocarbonyl thio end group of a RAFT polymer is readily transformed into a thiol via either reduction (for instance with NaBH₄ in water) or aminolysis in the presence of primary amines.³ The chemistry of thiols is very well documented, especially in biology and biochemistry, for instance, via reactions on cysteine, a thiol-containing amino acid, to introduce conjugates or functional groups along the backbone of peptides and proteins. In macromolecular chemistry, the thiol functionality has proved to be a versatile handle to introduce functionalization onto polymeric materials, as it is capable of reacting in high yields and mild reaction conditions with other thiols, maleimides, iodoacetamides, alkenes, acrylates (via Michael addition), alkynes (via double addition to the triple bond), and isocyanates.⁶⁸ The selectivity, rapidity, and high yields of such reactions have led some researchers to classify them as *click* reactions. However, there are severe limitations—at least for the radical variant—of thiol-ene chemistry for polymer–polymer conjugation (see **Radical Thiol–X Click Chemistry**).⁶⁹ Thus, we classify thiol-ene and thiol-yne chemistries in here as convenient RAFT-derived conjugation protocols, specifically suited for the conjugation of small molecules, rather than as fully fledged click chemistries. The overall synthetic approach exploits the ubiquity of the thiocarbonyl thio group, which controls both polymer synthesis and postpolymerization functionalization, two orthogonal relay reactions. The key aspects of such an approach are that the polymerization mediator, that is, the thiocarbonyl thio moiety, also behaves as a protecting group for the thiol functionality and the resulting thiol can be used for a ligation reaction that is undertaken in very mild conditions (e.g., ambient temperature) and often does not require a catalyst.

Drawbacks of the thiol-ene/yne approach include the typical issues associated with the use of the living end of the polymeric chains (termination events occurring during radical polymerization lead

to polymeric chains without ω -functionality); the fact that there will not be a quantitative transformation of the thiocarbonyl thio groups into thiols (although yields are high) and the potential for side reactions of the thiol end groups. Indeed, thiol–thiol coupling between two polymeric chains can occur in solution to form disulfide bridges. These side products are readily observed as shoulders at twice the molecular weight of the initial polymers on SEC analyses. Such side reactions are, in particular, preponderant for small polymeric chains. In the case of acrylic and methacrylic polymers, the terminal thiol group has also been observed to undergo intramolecular transesterification to yield terminal thiolactones at the polymer chain end.⁷⁰ A potential solution to prevent this problem, although not always practical, is to end-cap the polymeric chains with a small number of styrene units.

6 END-GROUP CHEMISTRY ON RAFT POLYMERS

End group chemistry can be finely controlled during the RAFT process based on the choice of the R- and Z-group. In addition, the thiocarbonyl thio end group can undergo a wide range of subsequent post-polymerization transformations, which have been reviewed previously in detail.^{71–74} Here, we will limit our discussion to those end group transformations that lead—in our view—to the most efficient removal of the RAFT group or introduce groups that can be effectively employed as starting points for the orthogonal conjugation of two polymeric chains or for the ligation of polymer strands to biomolecules. An overview of the most reliable and workable end group transformations is provided in Scheme 11. Note that transformations employing thiocarbonyl thio end groups themselves for end group modification are discussed in the section below on ligation protocols.

When functionality is to be introduced into a polymer via the RAFT process by virtue of the RAFT agent, this can either proceed via the Z- or R-group. Both approaches have been explored in detail. Introduction of functionality via the R-group provides a very efficient, and most importantly permanent, approach to end group functionalization. There is no danger of hydrolysis or elimination of the end group since it is tethered to the polymer terminus via a robust C–C single bond that is

Scheme 11 Reliable strategies to introduce end groups to or remove end groups from RAFT polymers. Note that the efficiency of the radical end group removal pathways depend on the individual RAFT agent as well as the leaving group ability of the polymer. The provided temperatures are typical values, which can vary in individual cases. The same holds true for the degrees of functionalization provided in the upper part of the figure for the Z- and R-group functionalization approaches.

formed during the reinitiation sequence. In addition, even those chains which do not carry a thiocarbonyl thio terminus can carry an R-terminus, allowing degrees of end group functionalization over 95% to be reached (the remaining 5% or less corresponds to those chains that have been initiated via an initiator-derived primary radical fragment and subsequently terminated in a bimolecular termination reaction). Introducing functionality via the Z-group consistently leads to lower degrees of functionalization, as the Z-group is attached to the thiocarbonyl thio moiety and can be the subject of elimination and hydrolysis reactions, especially at higher conversions. An interesting case, unique to the RAFT process, arises when the Z-group is attached to a solid support, either during or after polymerization. In this case, the products of the termination reactions (from either combination or disproportionation) lose their attachment to the support (since they lose their “living” end) and a simple filtration permits the separation of dead polymeric chains from living chains, which remain attached to the solid. Such an approach has been employed to generate highly pure living polymers⁷⁵ and multi block copolymers.⁴⁶ The most common types of functionalities introduced via the Z- and R-groups include carboxylic acids,⁷⁶ alcohols⁷⁷ and fluorescent markers,⁷⁸ but also carbohydrates⁷⁹ as well as proteins.⁸⁰

It is also possible to have an agent containing a long hydrophobic R-group which when polymerized with a hydrophilic monomer forms an amphiphilic system.⁸¹

The removal of the RAFT end group can be important for a range of applications as it gives the polymer a distinct color (ranging from red/pink to yellow). In addition, thiocarbonyl thio groups are always in danger of hydrolysis to thiols over longer periods in service, potentially giving rise to odor problems. Among the most efficient and reliable pathways for RAFT end group removal (i.e., the complete elimination of all sulphur from the polymer) are thermal elimination and radical reaction sequences.

Thermal elimination is the simplest removal tool, yet the macromolecular backbone has to withstand temperatures exceeding $100\text{ }^{\circ}\text{C}$. Several examples have demonstrated that thermolytic end group removal can be highly efficient with little effect on the molecular weight distribution.⁸² An added advantage is the fact that the resulting ω -end group functionalization can be employed in further reactions, including the use of the polymers as macromonomers. Removal of the thiocarbonyl thio end group via means of radical replacement has become very popular due to its high efficiency, generally low reaction temperature and

ease of use. The simplest approach merely involves the stirring of the RAFT polymer in a solution of tetrahydrofuran, in air, in the presence of a small amount of radical initiator, at low temperatures (see Scheme 12b).⁸³ During such a procedure, a hydroperoxide end group is initially generated,

which can be subsequently and readily be reduced to a hydroxyl group (using triphenyl phosphine or an alternatively suitable reducing agent). The transformations have been shown to be highly efficient with trithiocarbonate-capped poly(acrylates) as well as styrene, yet dithioesters also give

Scheme 12 Two principle mechanisms to remove the RAFT end group from the polymer. (a) Reaction sequence to recycle the thiocarbonyl thio end group of a RAFT-made polymer and yield an end-functional polymer via radical addition. In this procedure, the RAFT agent is recycled when $R^1 = R$. [(a) Reproduced with permission from Ref. 85. Copyright 2005 American Chemical Society.] (b) Reaction sequence for the transformation of RAFT-made polymer into hydroperoxy terminal species (which can be readily reduced to hydroxyl-capped polymers) via the addition of molecular oxygen to the freed macroradicals. [(b) Reproduced from Ref. 83a. © CSIRO Publishing, 2009.]

satisfactory results. If a symmetrical trithiocarbonate is employed, the molecular weight distribution of the polymer halves during the procedure. Problems and nonefficient transformations occur if poor leaving group chains are attached to the RAFT terminus (such as poly(vinyl acetate)). Occasionally the removal of the reducing agent can be difficult, depending on its nature (e.g., when it precipitates in the same solvent as the polymer). A detailed mechanistic description of the process can be found in Ref. 83. The provision of hydroxyl functionality using this procedure opens up an avenue for a range of follow-up chemical transformations, including the sulfur-free switch to other polymerization protocols.⁸⁴ A more versatile procedure is the introduced primary radical replacement process proposed by Perrier and coworkers that not only provides sulphur-free polymers but also allows for the recovery of the RAFT agent (see Scheme 12a). Addition of an excess of free radical initiator to a RAFT polymer leads to the preferred fragmentation of the intermediate radical to form a new RAFT agent (in which the R-group is the radical initiator) and a radical polymeric chain, which reacts in turn with the excess of initiator radicals by combination. The products of the reaction are therefore a new RAFT agent, ensuring the recycling of the thiocarbonyl thio group, and a polymeric chain, which is end-functionalized with the radical initiator.⁸⁵ In this approach, not only does the polymer product lose the color induced by the thiocarbonyl thio group but also it can be efficiently end-functionalized. To obtain optimal yields, care must be taken in the choice of the radical initiator, to favor the fragmentation of the polymeric chains from the intermediate radical. In cases where the recovery of the thiocarbonyl thio group is not required and/or the polymer end group functionalization is not sought, the removal of the thiocarbonyl end group can be achieved by using a source of radicals in association with a good H-donor molecule (e.g., isopropanol) to replace the thiocarbonyl thio end group with a hydrogen.^{82a} As in all radical processes, potential side reactions include the generation of polymeric chains from the termination (disproportionation and combination) of two macromolecules carrying a radical terminus. In the case of terminations by combination, these bimolecular termination fractions are evident as shoulders at twice the molecular weight of the initial polymer.

7 THE PROCESS OF RAFT POLYMERIZATION: HOMOGENEOUS AND HETEROGENEOUS POLYMERIZATIONS

One of the most advantageous aspects of RAFT polymerization is the versatility of the technique and thus its applicability to a wide range of reaction conditions. RAFT can successfully exert control over polymerization reactions in bulk (monomer), solution (both in organic or aqueous phase) as well as in heterogeneous systems. While RAFT reactions in bulk or organic solvents have been reported extensively since the inception of RAFT over a decade ago, it is the application of RAFT agents in heterogeneous media or aqueous phase that highlights the versatility of the process.

Homogeneous RAFT polymerization in bulk or solution can usually be performed under similar conditions as conventional free radical polymerization. Indeed, as long as the RAFT agent is fully soluble in the solvent, the RAFT agent can be expected to perform as required. In solution, RAFT polymerization has been conducted in a wide range of media from the more conventional organic solvents³ and water,⁸⁶ to less-conventional media such as ionic liquids⁸⁷ and supercritical fluids.⁸⁸

7.1 Aqueous RAFT Homogeneous Polymerization

The special case of aqueous homogeneous RAFT polymerization has received particular interest due to the ability to synthesize water-soluble polymers that can be useful for biomedical applications, for example. In addition, the environmental advantages of performing polymerizations in water (as opposed to organic solvents) have also been a driving force behind this research. However, in aqueous RAFT polymerization a number of factors must be considered. Thiocarbonyl thio compounds are susceptible to hydrolysis, both acid and base catalyzed. The hydrolysis has been shown to be more pronounced for the original RAFT agent (as a small molecule) than for a macro-RAFT agent, presumably due to protection of the RAFT group by the polymer chain in the later case.⁸⁹ This highlights the fact that in order to achieve a well-controlled polymerization and maintain high

end-group fidelity, the pH of the aqueous solution must be considered both before and during the polymerization.

In addition to the problems of RAFT agent hydrolysis in aqueous solution, aminolysis of the thiocarbonyl thio group can also occur to yield thiol-terminated polymers. This can become a problem if the monomers themselves are prone to hydrolysis and hence yield primary or secondary amines which then react with the RAFT agent. Of particular note are the acylamido monomers, which tend to show little control when polymerized by RAFT in water. These reactions have been studied extensively by the group of McCormick and equations have been developed to determine the extent and effect of both hydrolysis and aminolysis.⁹⁰ They demonstrated the degradation of dithiobenzoates by showing that in aqueous solutions buffered to pH 5.5 and 7.0, when the ammonia concentration was set at 5×10^{-3} M, the fraction of 2-cyano-pentanoic acid dithiobenzoate that remained after 8 h under such conditions was approximately 0.7 and 0.4, respectively. Nonetheless, as long as the reaction conditions are carefully considered before polymerization then water soluble polymers can be synthesized successfully using RAFT in aqueous solution.⁸⁶

RAFT polymerization in dispersed systems provides a methodology for developing particles having well-defined size and size distribution, while simultaneously controlling the molecular weight and polydispersity of the (co)polymer. In this way, block copolymer particles can be formed that exhibit interesting microstructures which can be finely controlled by correct selection of reaction conditions. RAFT-controlled heterogeneous polymerization has been reported using a variety of techniques, namely emulsion, microemulsion, miniemulsion, dispersion, and precipitation polymerization.⁹¹ The application of RAFT, particularly in emulsion polymerization, has generated intense interest due to the challenges associated with RAFT and the enhancement of factors such as Ostwald ripening, so-called “super-swelling” and the importance of entry-exit kinetics in the RAFT process.⁹² In addition to the ability to form well-defined particles of potential industrial use (in applications, e.g., as coatings, adhesives, sealants, biomedical devices, and so on), heterogeneous polymerization conditions provide a unique environment in which to investigate aspects of the RAFT mechanism (e.g., the fate of intermediate radicals) and as such this has been the focus

of much research. The remainder of this section will look at each of these heterogeneous processes individually and highlight important aspects of the RAFT process in each section—particularly with regards to challenges and problems that have been encountered. Unless otherwise stated, water is the continuous phase.

7.2 *Ab Initio* Emulsion Polymerization

As the name suggests, *ab initio* emulsion polymerization involves incorporation of all components of the polymerization—water-insoluble monomer, water-soluble initiator, surfactant, and water—at the beginning of the reaction. Upon the application of shear, both monomer droplets stabilized as micelles (typically in the range of 20 nm) and large monomer pools are formed.⁹² Following initiation, the polymerization proceeds in the aqueous phase until the polymer chain reaches a critical molecular weight and the chain enters a monomer-swollen droplet, and propagation then freely occurs; this is termed *interval I* (as originally defined by Smith and Ewart⁹³) and refers to the nucleation stage of emulsion polymerization. The subsequent *interval II* refers to the particle growth regime when there are no more micelles in solution, but the monomer-swollen particles are continuously fed from the monomer pools. Finally, *interval III* refers to the point when there are no more monomer pools remaining and conversion slows due to consumption of the monomer within the droplets. These regimes are depicted schematically in Scheme 13 as originally described by Smith and Ewart (adapted from Ref. 94).

Entry and exit of the RAFT agent is of upmost importance if the molecular weight is to be controlled in emulsion polymerization. RAFT agents will typically reside on the chain end of polymers during most of the polymerization and hence partitioning into the aqueous phase becomes less likely during reaction; this is very different from nitroxides and metal complexes used in NMP and ATRP, respectively, which likely partition to a greater extent because of their smaller size. Additionally, nucleation of particles in emulsion polymerization using RAFT should occur in the same way as in standard free-radical polymerization. Nonetheless, considerable complications concerning colloidal stability have been encountered. The very first example

Scheme 13 Cartoon depicting the three intervals in standard emulsion polymerization. [Adapted from Ref. 94. © Elsevier, 1995.]

of RAFT being used in an emulsion was reported by CSIRO in their original RAFT patent.¹ Following this report, extensive investigations from many research groups have highlighted the importance of understanding the transport kinetics of the RAFT agent during reaction. Almost all reported successful RAFT-controlled emulsion polymerizations have involved the use of xanthates—the success being attributed to the much lower reactivity compared to other RAFT agents ($C_{tr} \sim 1$) and therefore decreasing the likelihood of colloidal instability due to superswelling. Unfortunately, the low C_{tr} of xanthates restricts the control over polydispersities.⁹⁵ Monteiro *et al.*⁹⁶ were able to partially overcome this issue by using a xanthate with a slightly higher C_{tr} and obtained $\overline{M}_w/\overline{M}_n$ of ~ 1.5 while maintaining colloidal stability. Numerous attempts to control *ab initio* emulsion using high- C_{tr} RAFT agents have been marred by poor colloidal stability and poor molecular weight control (and high PDI). Work by both Nozaria and Tauer⁹⁷ and Monteiro and colleagues⁹⁸ have highlighted the importance of RAFT agent hydrophilicity, *in situ* degradation of RAFT agent, and, of course, transport kinetics in controlling both the molecular properties of the polymer and the colloidal stability of *ab initio* emulsions.

7.3 Seeded Emulsion Polymerization

To overcome some of the issues associated with nucleation and stability in *ab initio* polymerization, a preformed latex “seed” can be used. In this way, the polymerization starts at intervals II or III. Numerous reports have been built on the original work by Monteiro *et al.*⁹⁹ and suggested that the transport of the RAFT agent to droplets must occur during the first few percent of conversion in order to obtain well-controlled polymerizations.¹⁰⁰ Others suggested that migration of the R-group from the droplet following fragmentation would also lead to poor control. Successful seeded emulsion polymerization was reported by Prescott *et al.*¹⁰¹ with good overall control of both molecular weight and colloidal stability; however, the inhibition and retardation effects typically associated with RAFT were exacerbated compared to the analogous reaction in a homogeneous solution. Georges and coworkers¹⁰² used acetone as an additive to aid particle formation via a precipitation mechanism. Acetone was removed from the mixture prior to polymerization. This approach yielded polymers with well-controlled molecular weight and polydispersity. Xanthates have also been used successfully in seeded emulsion polymerization in many instances.¹⁰⁰

7.4 Mini Emulsion Polymerization

RAFT-controlled mini emulsion polymerization has also been extensively investigated. Since the methodology minimizes the reliance on transport kinetics of the RAFT agent, good control has often been observed. The disadvantages of mini emulsions are the necessity for high concentrations of surfactant compared to *ab initio* emulsion polymerization as well as the requirement for cosolvents. The formation of a mini emulsion requires mixing of all of the components of the reaction followed by reduction of the droplet size using mechanical shear. This is often accompanied by ultrasonic homogenization to yield small droplets that are generally stabilized against particle growth (depending on the surfactant concentration). Polymerization is then started via conventional means.

In initial experiments, RAFT-controlled mini-emulsion polymerization tended to exhibit the same frustrating destabilization that was observed in *ab initio* emulsion polymerizations. Good control could generally be maintained only up to around 30% conversion for styrene and, while some other acrylates showed more promise, large polydispersities were still observed.¹⁰³ Luo developed a theoretical model to describe the inefficiencies of ionic stabilizers in RAFT mini emulsion polymerization.¹⁰⁴ They postulated that, in the absence of early equilibration of the chemical potential between droplets and particles, superswelling would occur leading to destabilization. This is a direct consequence of the lack of high molecular weight polymer in living polymerizations at low conversion, since RAFT-capped oligomers would be expected to swell to a much greater extent than high molecular weight polymer that would exist in conventional polymerization. Luo *et al.* suggested that more stable latexes could be formed in the presence of larger particles, higher cosurfactant levels, and lower concentration of RAFT agents.¹⁰⁴

It was later found that, if a nonionic surfactant was used (e.g., Brij 98), then polymers with well-defined molecular weight were formed with no loss of colloidal stability.¹⁰⁵ This was attributed to the ability of Brij 98 to stabilize a much greater surface area than SDS and also its ability to inhibit monomer transportation. As was observed with *ab initio* polymerization, rate retardation compared to reactions in the absence of RAFT was also observed.

This has been attributed to both intermediate radical termination and slow fragmentation.

In general, deviation from expected RAFT properties (i.e., control over molar mass and PDI) in mini emulsion is attributed to the superswelling theory and this can be mediated either by using a nonionic surfactant or by incorporating significant amounts of costabilizer into the reaction when ionic surfactants are used. Nonetheless, there have been extensive reports of successful, RAFT-controlled mini emulsion polymerizations that maintain acceptable colloidal stability using both ionic and nonionic surfactants; many of these are summarized in the literature.¹⁰⁰

7.5 Microemulsion Polymerization

Microemulsions are thermodynamically stable emulsions of two immiscible liquids with monomer-swollen droplets in the size range 5–10 nm. Typically, these droplets form spontaneously in the presence of stabilizer without the addition of shear. In theory, the polymerization is localized within the droplet and, as is the case for a miniemulsion, there is no need for transportation of controlling agents through the aqueous phase since the monomer droplets will form polymer particles. However, in practice it has been shown that the number of droplets far exceeds the number of particles that are formed and so microemulsions act more like standard emulsions (i.e., droplets feed nucleated particles). For the special case of controlled polymerization in microemulsions, it has been suggested that compartmentalization of RAFT agents may have an effect on the polymerization since different particles contain different numbers of RAFT agents—this is important owing to the small size of the droplets and can often lead to tailing in the molecular weight distributions.

The use of RAFT in microemulsion has only been briefly investigated. For example, Kaler and coworkers¹⁰⁶ showed that hexyl methacrylate could be conducted under microemulsion conditions to yield particles in the size range of 18–30 nm. Under carefully chosen reaction conditions, good RAFT characteristics were observed. However, once again, long inhibition times and rate retardation were observed if the RAFT concentration was high. Other recent publications have demonstrated

RAFT-mediated microemulsion polymerization of polystyrene¹⁰⁷ and inverse microemulsion polymerization of dimethylacrylamide.¹⁰⁸ Kaler recently investigated compartmentalization of various RAFT agents in microemulsion polymerization.¹⁰⁹

7.6 Dispersion Polymerization

RAFT-controlled dispersion polymerization has also been reported. In dispersion polymerization, the initial system is homogeneous and polymer particles are formed once the chains reach a critical molecular weight and are stabilized by the addition of a surfactant. Typically, micrometer- to submicrometer-sized particles are formed. The most commonly used solvents for dispersion polymerization are hydrocarbons (alkanes), and in some cases alcohols or alcohol/water mixtures have been employed.

Styrene has been polymerized via dispersion polymerization using RAFT by various research groups in numerous solvents.¹¹⁰ Typically, a two-stage reaction sequence is required in which the RAFT agent is added to the polymerization after particle nucleation. When the two-stage approach is used, polymers with narrow PDI and controlled molecular weight are obtained. If the two-stage approach is not used, then the RAFT agent acts to broaden the particle size distribution because of extended nucleation times; this is related to the fact that RAFT agents keep all chains at relatively low molar mass compared to dispersion polymerization by conventional free-radical polymerization. Scanning electron microscopy images shown in Figure 5 highlight the particle size distribution observed in standard styrene dispersion polymerization in ethanol using 12 wt% poly(*N*-vinylpyrrolidone) (PVP) as stabilizer and the effect of using the two-stage approach. Clearly, when the latter approach is used, the particle size distribution is much smaller than when just the normal dispersion approach is taken.

Howdle and coworkers¹¹¹ used supercritical CO₂ as a solvent to conduct dispersion polymerization of methyl methacrylate and showed that good control over molecular weight and PDI could be obtained while colloidal stability was maintained. This was achieved in the absence of the two-stage methodology.

Dispersion polymerization using macro-RAFT stabilizers has also become popular. This is mainly

Figure 5 (a) Scanning electron microscopy images showing particles sizes and size distribution for dispersion polymerization of styrene in ethanol with PVP as surfactant in absence of RAFT agent; (b) with preaddition of RAFT agent at 4 h; (c) preaddition of RAFT agent at 24 h; (d) two-stage process at 4 h; (e) two-stage process at 24 h. [Reproduced with permission from Ref. 110b. © John Wiley and Sons, 2007.]

because the “surfactant” is covalently bound into the particles and cannot migrate and diffuse when the final polymer particles are used in future applications. In these experiments, the RAFT agent self-assembles into a particle *in situ*. Some notable examples have been demonstrated by the groups of Charleux,¹¹² Zheng and Pan,¹¹³ Bathfield *et al.*,¹¹⁴ and Youk.¹¹⁵ Additionally, Howdle and coworkers¹¹⁶ have shown that dispersion polymerization using macroRAFT is effective in supercritical CO₂ where CO₂philic macroRAFT agents containing polydimethylsiloxane or perfluoropolymers have been utilized. Other variations on this theme involve cross-linking of the dispersed polymer particles *in situ* to form insoluble particles.

7.7 Surfactant-Free Emulsion

RAFT polymerization in dispersed media was further improved by the team at the Key Centre for Polymers and Colloids,¹¹⁷ who developed an

Scheme 14 Structures of surface-active RAFT agent used by Choe *et al.*¹²¹ and IL-tethered RAFT agent used by Puttick *et al.*¹²²

approach to RAFT emulsion based on self-assembly techniques. In this approach, RAFT-terminated polymer chains of a hydrophilic species (e.g., acrylic acid) are initially formed in solution, followed by starved-feed of a hydrophobic monomer. This leads to the well-controlled growth of the hydrophobic monomer due to confinement of the RAFT group at the reaction locus upon formation of micelles. The authors were able to demonstrate a well-controlled polymerization with well-defined particles. The same group then showed that a block copolymer of styrene and acrylic acid that was terminated with a RAFT agent would also act to nucleate particles. They investigated the effect of hydrophobicity, for example, of the surfactant on block copolymer migration during particle nucleation.¹¹⁸ This approach revolutionized the development of RAFT emulsion polymerization, as it permits the manufacture of well-controlled polymeric particles exhibiting a range of morphologies and functionalities, including a route to efficiently encapsulate solids and liquids¹¹⁹ in a simple, surfactant-free process. Further developments exploiting this approach have led to numerous polymer systems being investigated and the formation of various core-shell particles. For example, Armes and coworkers recently used RAFT-terminated glycerol methacrylate as a steric stabilizer to form particles in the size range 20–100 nm with good size control.¹²⁰

7.8 Other Interesting Heterogeneous Systems

Choe and coworkers¹²¹ used a specially designed RAFT agent that acted as initiator, stabilizer, and chain transfer agent at 80 °C (4-thiobenzoyl sulfanylmethyl sodium benzoate (TBSMSB), Scheme 14). In these reactions, colloidal stability was maintained and polymers exhibiting good molecular weight control were observed (PDIs

ranging from 1.21 to 1.43). More interestingly, polymers exhibiting very high molar mass were observed (~400 kDa) while maintaining molecular weight monodispersity.

Thurecht and coworkers¹²² designed a surface-active RAFT agent to control heterogeneous polymerization in ionic liquids (ILs). In certain cases, poorly controlled RAFT polymerization was observed for methyl methacrylate in some ILs. An IL-tethered RAFT agent was synthesized (Scheme 14) and this facilitated much greater control over polymerizations yielding an experimental $\bar{M}_n$ much closer to the theoretical value. The authors postulated that the polymerization was occurring in a pseudomicroemulsion-type system and localization of the RAFT agent at the locus of polymerization was required.

In the realm of surfactant-free polymerization, RAFT polymerization employing the degassing technique has also received some recent interest. Following from the initial polymerization of styrene in the absence of the controlling agent, Hartmann *et al.*¹²³ showed that well-defined polymers with relatively narrow particle size distribution could be synthesized. The stable latex was formed by consecutive freeze-pump-thaw cycles and Ostwald ripening was minimized by addition of hexadecane. These authors attribute the stability of the system to the hydroxyl anions on the surface of the particles.

An interesting phase-inversion approach was reported by Charleux and coworkers¹²⁴ as a method of forming a stable emulsion. Bulk polymerization of styrene and acrylic acid (~80:20 molar ratio) was conducted to low conversion, followed by phase inversion by addition of aqueous sodium hydroxide. This generated a dispersed monomeric (organic) phase which could then be polymerized under “seed-like” conditions. Good control and colloidal stability were observed (PDI ~1.2, particle size = 140–180 nm).

7.9 Unique Morphologies from Heterogeneous Polymerization

RAFT control over heterogeneous polymerization facilitates the development of many interesting and useful morphological variations with applications ranging from impact modifiers in sheets to biomedical polymers. Importantly, the molecular weight control that RAFT imparts to any given polymerization can be used to tune the system for a desired morphology: for example, the development of core-shell, salami, or raspberry-type structures.¹²⁵

Klumperman and coworkers¹²⁶ utilized the miniemulsion technique to synthesize hollow-sphere polystyrene particles. These particles were formed because of the localization of polymerization at the interface of isooctane and water using an ionic potassium persulfate (KPS) initiator. The use of a RAFT agent that did not show retardation was required in order to achieve hollow particles. Numerous other authors have expanded upon this approach to develop hollow particles. For example, Luo and Gu¹²⁷ developed a dual control agent and surfactant that confined the RAFT to the surface of the particle. In Figure 6, the particles have been formed using SDS as a cosurfactant.

On the micrometer scale, Howdle and coworkers^{116b} developed a macroRAFT agent that acted as both CTA and stabilizer to undertake dispersion polymerization of MMA in

supercritical CO₂. The fluorophilic polymer 1*H*,1*H*,2*H*,2*H*-perfluorooctyl methacrylate was polymerized under bulk conditions using RAFT to a molecular weight of 8 kDa. This was then used as macroRAFT stabilizer in a dispersion polymerization. Transmission electron microscopy showed that the resultant particles had a clearly defined fluorine-rich shell.

8 CONCLUSIONS

The present article has highlighted the main strengths and limitations of RAFT chemistry. Key strengths of the RAFT process include its high tolerance to functional groups and reaction media, its non-rate-retarding nature, as well as its ability to control the molecular weight during a free-radical polymerization. The wide range of end groups and conjugation chemistries developed for thiocarbonyl thio-capped polymers allows it to be employed in efficient conjugation chemistries under mild and partially catalyst-free conditions. While there are a number of promising examples, there still exist substantial challenges in the form of the full development of a universal class of RAFT agents and their application toward a wide variety of monomer systems with disparate reactivities. For instance, exact control over the polymerization of ethylene under conditions of elevated pressure and temperature is highly desirable and, although notable attempts have been made, is still an important target of RAFT polymerization, as it requires RAFT agents that can not only form low-stability intermediate radicals upon the addition of high-reactivity ethylene propagating radicals but are also stable up to high temperatures ($T > 140^{\circ}\text{C}$) for extended periods. Of high importance, especially for the processability of the RAFT polymers, is a detailed understanding of their thermal stability, for example, of Z-group-generated star polymers. Such an understanding on a systemic level (via a variation of the RAFT agent structures in Z-group architectures) is still lacking to a large degree and may prove to be vital for the bulk processing of RAFT-made, complex-architecture polymeric materials.

Within the realm of modular polymer conjugation, the advent of transformations that exploit the presence of the RAFT end group in an atom-economical fashion has opened the possibilities for direct conjugation of RAFT polymers to

Figure 6 Hollow polystyrene particles formed by emulsion polymerization using a surface-active RAFT agent in the presence of additional SDS surfactant. [Reproduced from Ref. 127b, Copyright (2007), with permission from Elsevier.]

variable diene structures via [4 + 2] cycloadditions. Although these reactions can proceed with high rates at ambient temperature to quantitative yields, other conjugation protocols involving the RAFT end group might be feasible with similar ease. In terms of process, the versatility of RAFT enables it to be expanded to large-scale industrial processes and to become a commercial reality, both for homogeneous and heterogeneous polymerization systems. However, RAFT still requires further developments in terms of sustainability¹²⁸ and to lower the cost of the reagents.

Nitroxide-Mediated Polymerization and its Applications

Didier Gigmes¹ and Sylvain R. A. Marque²

¹Centre National de la Recherche Scientifique, Marseille Cedex, France and ²Aix-Marseille Université, Marseille Cedex, France

1 INTRODUCTION

Radical polymerization has been a tool for industry since the mid-twentieth century.¹ Nevertheless, controlled radical polymerization emerged during the last 3 decades, mainly as four techniques: degenerative transfer (see **Fundamentals of Controlled/Living Radical Polymerization**), atom transfer radical polymerization (ATRP, see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**), reversible radical addition transfer fragmentation (RAFT, see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**), and the stable free radical polymerization (SFRP).² This article is devoted to the kinetics and subsequent limitations of nitroxide-mediated polymerization (NMP) (one of the most popular SFRP techniques) as well as the various applications of advanced polymers prepared with this technique. Several sections are devoted to the kinetic behavior (homolysis, reformation, and side-reactions) of alkoxyamines (initiator/controller) and macroalkoxyamines (so-called “dormant species”). Although the term *living polymerization* is sometimes discussed,^{3,4} for the sake of simplicity and as this term is commonly used in the community, it is preferred to pseudo-living

polymerization.⁵ Clear and supporting arguments are provided by Rizzardo and Moad in their book in favor of the use of controlled/living radical polymerization.⁶ All alkoxyamines, nitroxides, and alkyl radicals mentioned in this article are gathered in Figure 1.

2 PRINCIPLE AND KINETICS OF NITROXIDE-MEDIATED POLYMERIZATION

Although the kinetic properties of alkoxyamines (R^1R^2NO-R) were reported in the mid-1970s,^{7–9} NMP was only discovered in 1985 by the Commonwealth Scientific and Industrial Research Organization (CSIRO) team,^{10,11} and was widely advertised by the seminal work of Georges in 1993.¹² Quickly, several authors pointed out the important role of the lability of the C–ON bond in alkoxyamines.^{13–15} In 1997, Fischer¹⁶ proposed that the kinetics of NMP was ruled by the unusual selectivities of radical reactions by internal suppression of fast modes¹⁷ *aka* persistent radical effect (PRE) (see **Nitroxides in Synthetic Radical Chemistry and Fundamentals of Controlled/Living Radical Polymerization**),¹⁸ and predictive

Figure 1 Species discussed in this article.

The PRE is a kinetic effect leading to unusual selectivities for radical reactions, that is, when several

Scheme 1 Persistent ($P\cdot$) and transient ($T\cdot$) radicals generated from a unique source (a), and from two sources (b).

types of radical are generated simultaneously, the fast reaction for coupling of (alkyl) radicals is suppressed, leading to observation of the predominance of the cross-coupling reaction up to a large extent or, in some cases, an unstable compound made to look stable. Even though this effect was first reported in 1936,²⁵ the kinetic equations describing this amazing selectivity were only developed in 1986 by Fischer (Scheme 1),¹⁷ and it found its first interesting applications in NMP.²⁶ The occurrence of this effect must comply with some of the following requirements¹⁷:

- two different types of radicals are involved;
- one must be more persistent than the other one;
- they must be generated at the same moment at the same rate (or very close rates).

It can be either a monocomponent (Scheme 1a) or a bicomponent (Scheme 1b) system.

Resolving the equations for these two systems leads to (1) showing that the concentration of persistent species obeys a $t^{1/3}$ law.

$$[P\cdot] = [PT]_0^{2/3} \times \left(\frac{3k_1^2 \times 2k_3}{k_2^2} \right)^{1/3} \times t^{1/3} \quad (1)$$

Unfortunately, recording this $t^{1/3}$ law is often a challenge because (i) it needs a persistent species readily monitored; (ii) the side-reactions readily spoil the ideal kinetic behavior; and (iii) the evolution of the diamagnetic species is too slow on time. One of the best models fulfilling all the kinetic requirements was reported in 1998, with alkoxyamine **1** as PT, k_d (k_1 in Scheme 1) as the C–ON bond homolysis rate constant, 2,2,6,6-tetramethyl piperidin-*N*-oxyl (TEMPO) **2** as

persistent nitroxide, cumyl radical **3** as transient radical, k_c as the cross-coupling rate constants between nitroxide and alkyl radicals (k_2 in Scheme 1), and k_t as the self-termination reaction rate constant of alkyl radicals (k_3 in Scheme 1).²⁷ It was shown that the decay of **1** was dramatically accelerated in the presence of a free alkyl radical scavenger (100% of **2** released in 3000 seconds at 79.2 °C, Figure 2a), whereas it was extremely slow in the absence of a scavenger (2% of **2** released in 30 000 seconds at 82.5 °C, Figure 2b) and **2** obeyed a $t^{1/3}$ law (1), as expected. Thus, experiments with scavengers showed fast homolysis of **1**, whereas experiments without scavengers showed that the recombination reaction was favored over the termination reactions (Scheme 1).

Then, it was possible to solve the kinetic equations for each species and to plot their evolution with time (Figure 3). The kinetic behavior of **1** exhibited three different regimes as follows:

- A first regime for less than 0.1 second where transient cumyl radical and persistent nitroxide are generated at the same rate obeying a law in t . During that time, the self-termination reactions for the transient radical occur, leading to an excess of persistent radical which is needed to set the quasi-equilibrium that rules the second regime.
- A second regime lasting around 175 days ($t \approx 10^7$ seconds) before significant decay of **1** (circa 20%) can be observed. During that time, the pre-equilibrium is set, and the growth of the persistent nitroxide obeys a $t^{1/3}$ law (1) and the decay of the transient cumyl radical obeys a $t^{-1/3}$ law.
- The third regime lasting around 4 centuries (!) to reach 99% decay of **1**. During that time, the decays of the alkoxyamine **1** (so-called dormant species) and of the cumyl radical obey a $1/t$ law.

More details on the development of the kinetic equations and the subsequent consequences are available in the reviews by Fischer,^{19–21,26} Goto and Fukuda,²⁴ and the recent update²⁸ made by Fukuda and Matyjaszewski.

2.1.2 Examples

Here is the (probably) first example reported by Bachman and Wiselogle²⁵ (Scheme 2a)

Figure 2 Thermolysis of **1** (a) in the presence of galvinoxyl as alkyl radical scavenger and (b) under PRE conditions. [Reproduced from Ref. 27. © Royal Society of Chemistry, 1998.]

highlighting the exceptional stability of pentaerythranes toward thermolysis. Note that several other reactions ruled by this effect were discovered during the last century as, for example, the famous Barton reaction.²⁹ An example of a bicomponent system exhibiting high selectivity is displayed in Scheme 2b. The photolysis of a *bis**tert*butylperoxide/*tert*butylhydroperoxide/1,4-cyclohexadiene solution³⁰ leads selectively to the formation of a mixed dialkylperoxide. The application of PRE to alkoxyamines is highlighted by the seminal report of Studer,³¹ and more examples are provided in the reviews by Fischer,²⁶ Studer,^{32–35} and Bertin *et al.*³⁶

2.1.3 Consequences

The examples reported and the kinetic evidence given by **1** exemplify nicely the importance of the PRE in controlling the reactivity and selectivity of highly reactive radical species. Recent applications in organic chemistry using alkoxyamines highlight how this effect can be applied to perform selective intermolecular reactions such as addition onto alkene^{37,38} or carbonylation (see **Nitroxides in Synthetic Radical Chemistry**).³⁹

Consequently, in an idealized case, such a long decay for an alkoxyamine makes it possible to perform polymerizations before significant loss of

Figure 3 Evolution of **1** and its subsequent radical species in log plot. $k_d = 2.3 \times 10^{-3} \text{ s}^{-1}$, $k_c = 9.1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, and $2k_t = 2.3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ were given at 83°C . [Reproduced from Ref. 27. © Royal Society of Chemistry, 1998.]

Scheme 2 Examples of applications of the PRE in synthesis.

livingness is noticed. However, for polymerization, it should be mentioned that the typical kinetic behavior due to the PRE might be hidden by side-reactions such as thermal self-initiation of monomer,⁴⁰ and also by the use of an extra amount of nitroxide,⁴¹ of extra conventional initiators,⁴² or of nitroxide-reducing agents.⁴³

2.2 Nitroxide-Mediated Polymerization

2.2.1 General Scheme

As soon as NMP was discovered, Johnson *et al.*⁴⁴ using numerical analysis showed that the conventional three-stage—initiation, propagation, and

termination—radical polymerization was the most suitable description for the NMP process (Scheme 3). However, most researchers⁶ accepted that the homolysis of the initiator should not be slower than the homolysis of the dormant species (macroalkoxyamine $\text{R}^1\text{R}^2\text{NOM}_n\text{R}$ in (6)) and thus, the role of the initiation stage on the fate of NMP was disregarded. It facilitated the development of the analytical kinetic equations linking the features of the polymer (chain length M_n , PDI, conversion) to the rate constant values for the reactions of the propagation and termination stages (*vide infra*). However, recent studies showed that a description of NMP involving three stages was more suitable to get deep insight into each of the factors affecting the fate of NMP.⁴⁵ Thus, the complete kinetic scheme (Scheme 3) is composed of three stages, with k_d and $k_{d,ds}$ the homolysis rate constants of the initiator $\text{R}^1\text{R}^2\text{NOR}$ (2) and of the dormant species (6), k_c and $k_{c,ds}$ the cross-coupling rate constants between the alkyl radicals (the initiating one $\text{R}^\bullet$ and the propagating one $\text{RM}_n^\bullet$) and the controlling nitroxide $\text{R}^1\text{R}^2\text{NO}^\bullet$ ((3) and (5), respectively), k_{add} the addition rate constant of initiating alkyl radical $\text{R}^\bullet$ onto monomer M (4), k_p the propagation rate constant of propagating radical $\text{RM}_n^\bullet$ (7), $k_{t,ds}$ the self-termination rate constants for C-centered radicals (8), k_{dD} the intramolecular proton-transfer (Cope-type elimination, (9)) rate constants for the initiator and the dormant species, k_{cD} the intermolecular H-transfer rate constants between nitroxide and C-centered radical (10) for both the

Scheme 3 Scheme of three-stage NMP.

dormant species and the initiator, and k_{dec} the rate constant for the self-decay of nitroxide or alkyl radical (11).

is fulfilled for most of the alkoxyamines used in NMP.

$$K \ll \frac{k_{c,ds}[\text{initiator}]_0}{k_t}, \quad K \ll [\text{initiator}]_0, \quad k_{d,ds} \leq k_{t,ds}[\text{initiator}]_0 \quad (12)$$

2.2.2 Key Equations

Using the core equations of PRE and assuming that the initiation stage has a minor effect on the fate of NMP, Fischer^{19–21,26} developed a set of equations based on $k_{c,ds}$ and $k_{d,ds}$, making it possible to predict the region in which the quasi-equilibrium conditions are fulfilled (12), that is, the quasi-equilibrium constant $K = k_{d,ds}/k_{c,ds}$ holds, and hence to develop equations giving the control (PDI, (13)), livingness

$$PDI_\infty = 1 + \frac{[\text{initiator}]_0}{[\text{monomer}]_0} + \left(\frac{\pi k_p^3 [\text{initiator}]_0}{k_{d,ds} k_{c,ds} k_{t,ds}} \right)^{1/2} \quad (13)$$

$$\phi = \left(\frac{2k_{d,ds}k_{t,ds} \ln \left(\frac{1}{1-\text{conversion}} \right)}{k_{c,ds}k_p[\text{initiator}]_0} \right)^{1/2} \quad (14)$$

$$t_{\text{conv}} = \left(\frac{\left(2 \ln \left(\frac{1}{1-\text{conversion}} \right) \right)^3 \times k_{t,ds}}{9 \times k_p^3 \times [\text{initiator}]_0} \times \frac{k_{c,ds}}{k_{d,ds}} \right)^{1/2} \quad (15)$$

(ϕ , (14)), and polymerization time (t_{conv} , (15)). From this set of equations, it is possible to build the so-called phase diagram (*vide infra*) and to predict the fate of NMP. As initiator concentrations are never higher than 0.1 M, as $k_{t,ds}$ values are higher than $10^6 \text{ M}^{-1} \text{ s}^{-1}$ (except at very high conversions), and as $k_{c,ds}$ values are often larger than $10^4 \text{ M}^{-1} \text{ s}^{-1}$, the quasi-equilibrium condition

2.2.3 Phase Diagram

With the equations displayed above, it is now possible to plot a phase diagram which shows different sections leading to NMP experiments of various qualities (Figure 4).^{20,21} The line QE borders the zone where quasi-equilibrium is achieved, that is, above this line there can be no living and controlled

Figure 4 Range of rate constants $k_{d,ds}$ and $k_{c,ds}$ for optimized NMP experiments in $t_{90\%} = 5$ hours (15) for 90% conversion with less than 2% unreactive polymer and PDI ($\delta = \text{PDI} - 1$, (13)) smaller than 1.2. $k_p = 5000 \text{ M}^{-1} \text{ s}^{-1}$, $k_t = 10^8 \text{ M}^{-1} \text{ s}^{-1}$, and $[\text{initiator}]_0 = 0.1 \text{ M}$. [Reproduced from Ref. 21. © Wiley-VCH Verlag GmbH & Co. KGaA, 2001.]

polymerization. The bold lined zone, where point A lies, corresponds to the zone for which the polymerization exhibits an ideal control and targeted high livingness in the required polymerization time. The zone below the bolded line T and above the dashed line δ ($\delta = \text{PDI} - 1$) will provide a living and controlled polymerization in a longer time than aimed. The zone below the dashed line δ and the thick line ϕ will provide a poorly controlled but living polymer in a time depending on line T. On the other hand, the zone below the dashed line δ and above the thick line ϕ will provide a poorly living and poorly controlled polymer, indicating, unsuccessful NMP experiment. Interestingly, going from A to B, the product $k_{d,ds} \cdot k_{c,ds}$ decreases the K value constant being constant, which implies that the same livingness and conversion at the same time is reached for B as for A, except that the polymer obtained for B will exhibit high livingness but poor control. Indeed, the PDI of 1.1 for A increases to 3 for B, keeping the dead fraction smaller than 2%. Going from A to C, the K value increases, keeping the product $k_{d,ds} \cdot k_{c,ds}$ constant, implying that the same PDI and the same conversion is reached for C in a shorter time than for A, except that the polymer for C will exhibit good control but poor livingness. Indeed, the dead fraction of 2% for A increases to 50% for C, keeping the PDI close to 1.1. Obviously for NMP, the properties of livingness and control do not mutually imply each

other.^{20,21} Importantly, it must be stressed that the construction of this diagram is based on an ideal case with no additional initial nitroxide, no additional alkyl radical generation, no side-reaction, and assuming the nonimportance of the initiation stage. The effect of the last two terms on the fate of NMP is discussed in Section 2.2.4. The effect of the addition of extra alkyl radicals has been thoroughly discussed by Fukuda *et al.*^{22,24,46} It can originate from intentionally added initiators, residual peroxide impurities, or from the auto-initiation of the monomer.

In the case where the additional alkyl radical generation rate r is slow, the equations displayed above still hold. The main consequences are that the polymerization is faster, the $t^{1/3}$ law is not obeyed but the conversion follows the more conventional t law (16) and other equations are also modified.²⁶ When extra initial nitroxide is added, the kinetics are also modified. The $t^{1/3}$ law is not obeyed any longer and replaced by a t law. The polymerization is slowed down, which helps to control the monomer exhibiting high k_p values.^{26,47}

$$\ln \frac{[\text{monomer}]_0}{[\text{monomer}]} = k_p \sqrt{\frac{r}{k_t}} t \quad (16)$$

2.2.4 Initiation Stage

As will be discussed later, NMP can be performed in bulk, solution, or dispersed media. Whatever the conditions, only three types of initiations are possible: monocomponent initiating system, bicomponent initiating system, and *in situ* polymerization. It must be noted that the monocomponent initiating system in bulk polymerization has been the most thoroughly investigated because it is the simplest system, and the most suitable to test and exemplify the equations developed.

Monocomponent Initiating System for Bulk or Solution NMP

For cases exhibiting $k_d \gg k_{d,ds}$ (in the case of $k_d \ll k_{d,ds}$, polymerization went from poor control to no control or inhibition), the theoretical models developed by Johnson *et al.*,⁴⁴ Fukuda,⁴⁸ and Fischer²⁶ describe the experimental observations concerning the kinetics of the polymerization, and the

evolutions of the mass, PDI, and living fraction (LF). It was recently shown that the initiation stage plays a pivotal role, that is, the higher the k_d , the better the control.^{45,49} In a recent study, Bagryanskaya *et al.*⁵⁰ reported that NMP of styrene was successful when the slow initiator **4** was used, whereas it failed when the fast initiator **5** was used although the same nitroxide controller **6** was involved. Edeleva *et al.*⁵¹ reported that around 3% of H-transfer occurred during the cross-coupling reaction of **7** with **6**. This kinetic behavior was also reported for a series of TEMPO-based alkoxyamines **8a–d**.⁵²

Thus, alkoxyamines with high k_d can be used for initiation only when the H-transfer reaction ((10), Scheme 3) cannot compete with the reformation reaction ((3) in Scheme 3) when the first addition of the initiating alkyl radical onto the monomer ((4), Scheme 3) is slow. More details have been provided in a recent review.⁴⁵

The other key reaction in the initiation stage is the first addition of alkyl radical onto the monomer (k_{add} , (4) in Scheme 3). The factors controlling the later have been thoroughly investigated over the last 4 decades, and a comprehensive review was published by Fischer and Radom.⁵³ The comments developed in this subsection are likely to hold for other initiating systems.

Oil-Soluble Monocomponent Initiating System for Miniemulsion Polymerization

Both molecular and macromolecular oil-soluble alkoxyamines have been successfully employed in miniemulsion polymerization. For example, chain extensions with *n*-butyl acrylate from polystyryl-TEMPO⁵⁴ or polystyryl-TIPNO-OH (*N*-(1,1-dimethyl-2-hydroxypropyl)-*N*-(2-methyl-1-phenylpropyl)-*N*-oxyl)**10**⁵⁵ macroinitiators afford an efficient route to the corresponding poly(*n*-butyl acrylate)-*b*-polystyrene diblock copolymer latexes. The more versatile SG1-based oil-soluble alkoxyamine **11** allowed better results to be obtained, as well-defined *Pn*BA homopolymers⁵⁶ and gradient copolymers⁵⁶ with styrene were obtained with solid contents up to 45 wt%.

Water-Soluble Monocomponent Initiating System for Miniemulsion Polymerization

Nicolas *et al.*⁵⁷ used the water-soluble BlocBuilder™ carboxylate salt alkoxyamine **12** to report the first example of a water-soluble

monocomponent initiating system in miniemulsion NMP.

Monocomponent Initiating System for Emulsion Polymerization

All successful results with molecular alkoxyamines concerned seeded systems in which the complex nucleation step has been circumvented. The first example was achieved when a polystyrene latex was allowed to swell with styrene and an oil-soluble, 2-based alkoxyamine.⁵⁸

A significant breakthrough has been witnessed with the use of water-soluble, **14**-based alkoxyamines **12** via a simple two-step emulsion process.^{59,60} The first step consists in obtaining low solid content seed latexes and preventing the formation of large droplet of monomer.⁵⁹ And the second step consists in the addition of a second load of monomer (either S or *n*-BA) in one part⁶⁰ or in a continuous fashion⁶¹ in order to target higher solid content by efficient chain extension.

Bicomponent Initiating System for Bulk and Solution NMP

On the other hand, an NMP experiment can be initiated using a system based on combination of nitroso^{62–67} compounds or nitrones^{62–64,68} and a conventional initiator. The *in situ* polymerization relies strongly on this approach and affords very good results concerning some monomers such as alkylmethacrylates.^{69,70} The conventional initiator releases radicals which add onto the monomer to generate second-hand alkyl radicals: one radical is scavenged by a nitroso compound or a nitron to afford a nitroxide which in turn scavenges another alkyl radical to yield an alkoxyamine which will play the final role of initiating/controlling species. The same approach is often applied using a bicomponent system combining nitroxide and conventional initiators. The important advantages of these approaches are the wide range of commercially available nitroso compounds, nitrones, and nitroxides, and the possibility of skipping the tedious step of preparation of alkoxyamines. Although the expected linear increase in M_n with the conversion has been reported, the unknown amount of *in situ* generated alkoxyamines makes it difficult to target a specific M_n .

Oil-Soluble Bicomponent Initiating System for Miniemulsion Polymerization

The first example that illustrates this approach, concerns the use of **2** in combination with benzyl peroxide for the polymerization of styrene at 125 °C and in the presence of camphorsulfonic acid as a rate accelerant.⁷¹ A good control was shown for M_n up to 40 000 g mol⁻¹ with PDIs in the 1.14–1.6 range. The use of **14** allowed the miniemulsion polymerization of styrene to proceed at a temperature below 100 °C.⁷²

Water-Soluble Bicomponent Initiating System for Miniemulsion Polymerization

In this case, the polymerization starts in the aqueous phase and leads to the formation of oligoradicals and oligomeric alkoxyamines which enter the monomer droplets, hence becoming the primary locus of polymerization. Macleod and coworkers achieved very fast polymerizations and low PDIs by selecting **2** and potassium persulfate (KPS) for the polymerization of styrene at 135 °C.⁷³ The success of miniemulsion NMP depends dramatically on the aqueous phase kinetics and on the partition coefficients of the nitroxides.⁷⁴ The use of the K₂S₂O₈/Na₂S₂O₅ redox initiating system in conjunction with **14** allowed the polymerization rate of styrene to be enhanced compared to its counterpart with azo-bis(isobutyronitrile) (AIBN) at 90 °C.^{72,75}

Bicomponent Initiating System for Emulsion Polymerization

The difficulties associated with an NMP process in a true emulsion systems were related to colloidal instability and/or poor control, mainly assigned to nucleation of the large droplets of monomer and nitroxide partitioning.⁷⁶

Among **2** and its derivatives under KPS initiation at 130 °C, only **15** led to stable latexes stabilized by sodium dodecyl sulfonate (SDS) with good control/livingness.⁷⁷ With K₂S₂O₈/Na₂S₂O₅ and **14** at 90 °C, the polymerization exhibited rather good control even though a certain percentage of coagulum was noticed.⁷²

2.2.5 Propagation Stage

The propagation rate constants k_p have been extensively and thoroughly investigated over the last

6 decades, and a comprehensive review has been recently published by Beuermann and Buback.⁷⁸ It does not deserve more comments, except that the k_p values will set $k_{c,ds}$ and $k_{d,ds}$ values through (13)–(15).

Using the core equations (12)–(15) shown above, it is possible to predict the control (PDI, (13)), livingness (ϕ , (14)), and polymerization time ($t_{90\%}$, (15)). From this set of equations, it is possible to build the so-called phase diagram and to predict the fate of NMP. For the sake of simplicity, $k_{d,ds}$ and $k_{c,ds}$ were assumed identical or close enough to the k_d and k_c of the corresponding alkoxyamine models (unimers) so that the predictive abilities of the phase diagram approach will not be altered. This held for macroalkoxyamines based on polystyryl chains, it was partly valid for poly-*n*-butylacrylate chains, and led to misleading prediction for polymethylmethacrylate (PMMA) chains as well as for random or statistical copolymers. As examples, phase diagrams for the NMP of styrene and *n*-butyl acrylate were plotted assuming no chain length effect (a plot taking into account chain length effect for poly-*n*-butyl acrylate-based alkoxyamine changed the figure slightly but did not modify the discussion and the conclusion drawn). Interestingly, the phase diagram (Figure 5a) predicts unsuccessful NMP of styrene at 120 °C with **14** (poor livingness), perfect NMP with **16**, and long time polymerization with **2** (but with the expected control and livingness). Experimentally, NMP was completely successful for these three controlling agents.^{41,49} In fact, side-reactions such as the instability of **14** and **16** modified the kinetic regime in a good way, and the auto-initiation of the styrene accelerated the reaction with **2**. On the other hand, successful NMP of styrene at 90 °C was only predicted for **14**. For **16** and **2**, control and livingness were predicted to be of good quality but with a dramatically long time of polymerization. Experimentally, the expected successful NMP with **14** was observed only when **12** was used as initiator (Figure 5a). For **2** and **16**, very sluggish polymerization has been reported.⁴¹

Unsuccessful NMP of *n*-butyl acrylate was predicted by the phase diagram for both temperatures and whatever the controlling agent (Figure 5b). This was confirmed experimentally and attributed to the high k_p value of *n*-butyl acrylate.^{10,41,49,79–81} This failure was overcome by adding a little amount of extra nitroxide^{41,82} or by developing new controlling

Figure 5 Phase diagrams for the NMP of styrene (a) and *n*-butyl acrylate (b) at 120 °C (red lines and symbols), and 90 °C (blue lines and symbols) with **2** (●), **16** (★), and **14** (■) as controlling agents. The dashed zone is where a perfect NMP experiment is expected. For (a) [alkoxyamine]₀ = 5 × 10⁻² M, $k_t(90 \text{ and } 120^\circ\text{C}) = 1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $k_p(120^\circ\text{C}) = 2000 \text{ M}^{-1} \text{ s}^{-1}$, $k_p(90^\circ\text{C}) = 900 \text{ M}^{-1} \text{ s}^{-1}$, $k_c(\mathbf{14} + \text{polystyryl radical}, 90 \text{ and } 120^\circ\text{C}) = 2.6 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$, $k_c(\mathbf{2} + \mathbf{20}, 90 \text{ and } 120^\circ\text{C}) = 2.0 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, $k_c(\mathbf{16} + \mathbf{20}, 90 \text{ and } 120^\circ\text{C}) = 8.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, $k_d(\mathbf{46}, 90^\circ\text{C}) = 3.4 \times 10^{-4} \text{ s}^{-1}$, $k_d(\mathbf{46}, 120^\circ\text{C}) = 8.0 \times 10^{-3} \text{ s}^{-1}$, $k_d(\mathbf{45}, 90^\circ\text{C}) = 3.6 \times 10^{-5} \text{ s}^{-1}$, $k_d(\mathbf{45}, 120^\circ\text{C}) = 10^{-3} \text{ s}^{-1}$, $k_d(\mathbf{19}, 90^\circ\text{C}) = 1.3 \times 10^{-4} \text{ s}^{-1}$, $k_d(\mathbf{19}, 120^\circ\text{C}) = 3.3 \times 10^{-3} \text{ s}^{-1}$. For (b) [alkoxyamine]₀ = 5 × 10⁻² M, $k_t(90 \text{ and } 120^\circ\text{C}) = 7.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, $k_p(120^\circ\text{C}) = 8.3 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, $k_p(90^\circ\text{C}) = 6.6 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$, $k_c(\mathbf{14} + \text{polyalkylacrylate radical}, 90^\circ\text{C and } 120^\circ\text{C}) = 2.8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, $k_c(\mathbf{2} + \mathbf{21}, 90 \text{ and } 120^\circ\text{C}) = 6.5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $k_c(\mathbf{16} + \mathbf{21}, 90 \text{ and } 120^\circ\text{C}) = 2.5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $k_d(\mathbf{11}, 90^\circ\text{C}) = 1.2 \times 10^{-4} \text{ s}^{-1}$, $k_d(\mathbf{11}, 120^\circ\text{C}) = 3.0 \times 10^{-3} \text{ s}^{-1}$, $k_d(\mathbf{22}, 90^\circ\text{C}) = 10^{-6} \text{ s}^{-1}$, $k_d(\mathbf{22}, 120^\circ\text{C}) = 3.3 \times 10^{-5} \text{ s}^{-1}$, $k_d(\mathbf{23}, 90^\circ\text{C}) = 1.9 \times 10^{-5} \text{ s}^{-1}$, $k_d(\mathbf{23}, 120^\circ\text{C}) = 5.8 \times 10^{-4} \text{ s}^{-1}$.

agents.^{83,84} However, for **2**, the improvement was not enough because of the H-transfer side-reaction which spoiled the NMP.⁸⁵ It was also shown that successful NMP of *n*-butyl acrylate was observed when the fast homolyzing alkoxyamine **12** was used.⁴⁹

With the conventional assumptions, the phase diagram predicted successful NMP of methyl

methacrylate (MMA) with **14** at 45 °C (Figure 6a).⁸⁶ However, the experiment performed under the recommended conditions failed.⁸⁶ It was shown that it was due to dramatic differences between k_d and $k_{d,ds}$ and between k_c and $k_{c,ds}$, which favored the intermolecular H-transfer between **14** and **37** although in very low amount. Several authors showed that intermolecular H-transfer was occurring with **14** and **37**

Figure 6 Fischer's phase diagrams for NMP of MMA: (a) controlled by **14** at 45 °C, (b) controlled by **14** at 75 °C with 8% of styrene, and assuming **24** as model of dormant species. (c) NMP of MMA with 8% of styrene controlled by **14** at 75 °C (● at 83 °C and △78 °C, $M_{n,th} \approx 35\,000$ g mol⁻¹). [(a) Reproduced from Ref. 86. © Wiley-VCH Verlag GmbH & Co. KGaA, 2006. (b) Reproduced from Ref. 45. © Royal Society of Chemistry, 2011. (c) Reproduced from Ref. 89. © American Chemical Society, 2006.]

although in very low amount (see Ref. 87). However, its occurrence plays a dramatic role during the NMP of MMA because due to very high k_d values and low k_c values, the H-transfer reaction becomes the preponderant termination reaction.^{86–88} In fact, when the chain length effect was taken into account (i.e., estimated for $k_{c,ds}$ and modeled for $k_{c,ds}$ using the penultimate unit effect (PUE) for $k_{d,ds}$, *vide infra*), the phase diagram predicted an unsuccessful experiment (Figure 6a), as experimentally observed.⁸⁶

It was reported that NMP of MMA was possible in the presence of some amount of styrene with **16**.⁴¹ Combining electron paramagnetic resonance

(EPR) investigations, kinetics analyses, and polymerization experiments, Charleux *et al.*⁸⁹ showed that **24** was the model for the dormant species. Furthermore, when a phase diagram was plotted with conventional assumptions, NMP of MMA with **14** was predicted to fail, whereas when the effect of the penultimate unit modeled by **24** was accounted for, NMP of MMA was predicted as being successful (Figure 6b,c). Consequently, to apply a phase diagram, it is strongly recommended to use $k_{d,ds}$ and $k_{c,ds}$ of the dormant species instead of k_d and k_c of the model alkoxyamine.

Unfortunately, only a few $k_{d,ds}$ and $k_{c,ds}$ are available in the literature. However, the chain length effect for $k_{d,ds}$ is mainly due to PUE, and can be

partly predicted. At this time, no trends are available for $k_{c,ds}$.^{58, 90–92}

2.2.6 Termination Stage and Side-Reactions

The conventional dimerization and disproportionation self-termination reactions of alkyl radicals were reviewed in the late 1980s,⁹³ and do not deserve more comments. The same termination reactions for polymeric radicals were reviewed a few years ago by Buback (see **Kinetics of Polymerizations**).⁹⁴ It is noteworthy that the termination rate constants k_t for polymeric radicals are in general several orders smaller than the corresponding ones for alkyl radicals. Importantly, these self-termination reactions are needed to set the PRE

Fischer.^{21,26,47,98} As a rule of thumb, 0.5% H-transfer has no influence on NMP which can tolerate up to 2% of H-transfer (80% conversion, 40% livingness). For a larger percentage of H-transfer, the NMP process is spoiled. Of course, these limits are modified depending on the conversion and the livingness targeted and the values of k_p , $k_{c,ds}$, and $k_{d,ds}$. When intermolecular H-transfer occurs, the decay of alkoxyamine is given by (17) with $f_{cD} = k_{cD}/(k_c + k_{cD})$ the disproportionation fraction, thus the maximal concentration C_{max} reachable, the optimal polymerization time t_p , and the LF are given by (18)–(20), respectively. Furthermore, the maximal f_{cD} tolerated to obtain a viable NMP experiment is given as a function of the conversion, LF, $k_{d,ds}$, $k_{c,ds}$, k_p , and k_t in (21).

$$[ds]_t = [\text{initiator}]_0 \times e^{-f_{cD} \times k_{d,ds} \times t} \quad (17)$$

$$C_{max} = 1 - \exp \left(-\frac{3}{2} \times k_p \left(\frac{[\text{initiator}]_0}{3k_{t,ds}(k_{c,ds} + k_{cD})k_{d,ds} \times f_{cD}^2} \right)^{1/3} \times 1.08 \right) \quad (18)$$

by generating an excess of nitroxide in the early stage, which in turn helps to maintain these termination reactions to a low level, leading to high livingness.^{20,24,26} To build a phase diagram, it is recommended to use the k_t values for the polymeric species when available.

The key termination reactions are the intramolecular (Cope-type elimination in Scheme 4 and (9) in Scheme 3) proton-transfer reaction,⁹⁵ which occurs during the thermal decomposition of the alkoxyamine, and the intermolecular (Scheme 4 and (10) in Scheme 3) H-transfer reaction,⁹⁶ which occurs during the cross-coupling between C-centered radicals and nitroxides.^{6,24,26,92,97} These reactions are most often invoked to explain why NMP failed.^{6,24,26,48}

The influence of these reactions on the fate of NMP was theoretically investigated by

$$t_p = \frac{1}{f_{cD}k_{d,ds}} \ln \left(\frac{1}{2.59} \times \frac{2}{1-p} \right) \quad (19)$$

$$LF = \frac{[ds]_{t_p}}{[\text{initiator}]_0} = e^{-f_{cD} \times k_{d,ds} \times t_p} \quad (20)$$

$$f_{cD} < \frac{\ln \left(\frac{1}{LF} \right)}{(2 \ln \frac{1}{1-C})^{3/2}} \times 3k_p^{3/2} \sqrt{\frac{[\text{initiator}]_0}{k_{d,ds}k_{c,ds}k_{t,ds}}} \quad (21)$$

It was shown that the effect of the intramolecular proton transfer (Cope-type elimination) was the same as for the intermolecular H-transfer and, consequently, the equations displayed above are suitable to predict the fate of NMP, except that the decay of the alkoxyamine (dormant species) is

Scheme 4 Cope-type elimination and intermolecular H-transfer reactions.

given by (17) with $f_{dD} = k_{dD}/k_{d,ds}$. Consequently, although from a practical view point, it is difficult to differentiate between these side-reactions, this leads to the same consequence: lower quality NMP. Edeleva *et al.* provided a procedure to differentiate these processes and investigated the kinetics when both were occurring (22).^{51,99}

$$[ds]_t = [\text{initiator}]_0 \times e^{-(k_{dD} + k_{d,ds}f_{cD})t} \quad (22)$$

Owing to very complicated kinetics, only few results are available to confirm the set of equations developed by Fischer and are presented here.^{92,100,101}

Despite their importance, these side-reactions have not been extensively investigated and, thus, their occurrence is often considered as a random event and depends a lot on the structure of the nitroxide, the alkyl radical/fragment, and the experimental conditions (*vide infra*). However, some trends can be drawn: (i) in general in the case of styryl radical, the H-transfer is negligible and does not hamper the polymerization^{6,24,26,85}; (ii) the H-transfer is more favored in the case of acrylyl radicals and not all nitroxides can afford controlled polymerization of this type of monomer^{26,85,97}; (iii) *H-transfer in the case of methacrylyl radicals occurs for most of the nitroxides making the NMP of MMA a challenge for chemists.*^{6,24,26,102}

Another side-reaction, the instability of the nitroxide ((11) in Scheme 3), may play an important role on the fate of NMP. Several authors have noted that the removal of nitroxide due either to its self-decomposition or to the presence of an additive shortened strikingly the polymerization time with no alteration of both control and livingness.^{41,43,103} Equations describing acceptable limits for NMP were developed by Souaille and Fischer.⁴⁷ *The interesting outcome of this analysis is that a very unstable nitroxide (a few seconds of lifetime) can be used to control the polymerization.* Furthermore, the evolution of each parameter very much resembles the evolution observed when a conventional initiator is added, implying that the livingness is only slightly altered. Amazingly, the occurrence of the (self-) decay of the nitroxide might balance the detrimental effect of the H-transfer reactions when suitable conditions are gathered. This very surprising aspect was confirmed and highlighted by Edeleva *et al.*⁵¹ with **25**. On the other hand, such behavior makes

the monitoring of H-transfer reaction quite elusive in some cases and, thus, leads to controversial results.^{86–88,104,105}

In another case, between the self-decay of nitroxide and the intramolecular decay, side-reaction of alkoxyamine has been a little investigated: it is the CO–N bond homolysis which occurs, in general, for an alkoxyamine exhibiting bond dissociation energy (BDE)(C–ON) larger than 140 kJ mol^{–1}. Alkoxyamines based on **26** were successfully applied to the NMP of MMA which exhibited very good control up to 80% conversion and good livingness.¹⁰⁶ Surprisingly, such nitroxide did not undergo the conventional decay reactions affording hydroxylamine.⁹⁹ In fact, the occurrence of the N–OC bond cleavage,¹⁰⁷ despite a rather low BDE(C–ON) around 126.0 kJ mol^{–1},⁹⁹ is likely to moderate the occurrence of intermolecular H-transfer by decreasing the amount of nitroxide.

2.2.7 Copolymerization

Kinetic and Theoretical Studies

2-Mediated copolymerization of styrene in the presence of various comonomers has been essentially studied by Zaremski *et al.*^{108–111} The activation/deactivation equilibrium constants for many of those systems have been experimentally determined and various regimes depending on the ability or not of the second monomer to undergo a controlled/living NMP have been discussed. Charleux *et al.* investigated the theoretical features of the activation–deactivation equilibrium in nitroxide-mediated copolymerization and applied it to the SG1-mediated copolymerization of MMA with a low percentage of styrene (typically in the 4–8.8 mol% range). Using this approach, the MMA/styrene (4–8.8%) system exhibited all the characteristics of living/controlled polymerization, that is, (i) the concentration of propagating radicals and the level of irreversible termination reactions occurring with the MMA/**14** system were low; (ii) isolated styrene units were, time to time, incorporated into the macromolecular chains and at the chain end enabling the reversible deactivation by **14**, and (iii) additionally, the MMA PUE enhanced deactivation of the so-formed alkoxyamine **24**.^{89,112,113} This technique was later expanded to a series of methacrylate monomers

such as methacrylic acid,¹¹⁴ poly(ethylene glycol) methyl ether methacrylate,¹¹⁵ ethyl and *n*-butyl methacrylate,¹¹⁶ *tert*-butyl methacrylate,¹¹⁷ glycidyl methacrylate,¹¹⁶ and methacryloyl galactose.¹¹⁸

Reactivity Ratios

Despite the recent theoretical analyses reported above, reactivity ratios were determined experimentally for various systems and did not show significant differences with those found in classical radical copolymerization. The polymerizations were essentially carried out under controlled/living conditions either because both comonomers were easily controlled or because the composition was such that the major comonomer exhibited controlled NMP with the selected nitroxide. Many examples are based on styrene with a variety of methacrylate and acrylate comonomers, mostly in the presence of **2** or **14**.^{117, 119–131}

3 MAIN FAMILIES OF NITROXIDES

In this section, the main nitroxides are presented, as well as their efficiency in NMP. The main limitations of these nitroxides are their commercial availability and the preparation methods.

3.1 TEMPO, 1,1,4,4-tetramethyl isoindolin-*N*-oxyl (TMIO), and Other Cyclic Nitroxides

The first nitroxides to be used for NMP have been **27** and other isoindoline derivatives prepared beforehand by Moad and Solomon *et al.*^{10,11,13} It showed some efficiency for the NMP of styrene but was of poor efficiency in the case of other monomers. A few years later, Georges *et al.*¹² promoted the interest in the use of NMP to prepare polystyrene using the commercially available nitroxide **2**. It showed good efficiency to control the polymerization of styrene and its derivatives but was of poor efficiency for alkyl acrylate derivatives.¹³² The NMP of MMA failed with **2**¹³³ except under harsh acidic conditions^{134,135} or when random copolymerization conditions were applied.¹³⁶ Many other cyclic nitroxides with 5- to 8-membered rings carrying four alkyl groups on both positions α were prepared to overcome these limitations. Most of

them were efficient for NMP of styrene, whereas only a few of them^{83,137–139} were efficient for the NMP of alkyl acrylates. Interestingly, most of these radicals were rather stable for a long time at temperatures higher than 120 °C (for **27**, $t_{1/2} \gg 40$ hours, for **2**, $t_{1/2} \gg 15$ hours),¹⁴⁰ which may very much slow down the polymerization.

3.2 TIPNO, DBNO, SG1, and Noncyclic Nitroxides

Noncyclic nitroxides are divided into two families: one for which six groups are attached to the carbons in α of the NO moiety, and one for which five groups and one hydrogen atom are attached to the carbons in α of the nitroxide moiety. The first family was promoted by Catala's *et al.*⁴⁰ and Goto and Fukuda's⁹² groups who showed that **28** was efficient for the NMP of styrene and also of alkyl acrylate monomers. This efficiency was due to a low BDE(C–ON). The second family with **16** and **14** as heads of the series was promoted by Tordo's group.^{141,142} The versatility of **16**, carrying an aryl group and a hydrogen atom on the same carbon α , for the polymerization of styrene, alkyl acrylates, and random copolymerization of MMA with few percent of styrene was exemplified by the Hawker/Braslaw groups,⁴¹ whereas the versatility of **14**, carrying a phosphoryl group and an hydrogen atom on the same carbon α , was exemplified by Tordo's^{49,143,144} and Gnagnou's⁸² groups for the NMP of styrene and alkyl acrylates, and by Charleux's and Bertin's groups⁸⁹ for the random copolymerization of MMA. At the same period, Catala *et al.*^{84,145} developed **29**, a nitroxide carrying a hydrogen atom and an alkyl sulfoxide group on the same carbon α , which was as efficient as **16** and **14** and exhibited very low BDE(C–ON). Beside a very low BDE(C–ON), **14**, **16**, and **28** exhibit also low lifetime at 120 °C, that is, $t_{1/2} = 15$ hours, $t_{1/2} = 11$ hours, and $t_{1/2} = 3$ hours, respectively, which is an advantage when performing fast NMP.¹⁴⁰

3.3 DPAIO and Other Aryl Nitroxides

The use of **26** was promoted by Greci's and Bertin's groups for the NMP of MMA.¹⁰⁶ Twenty

years after the discovery of NMP, **26** was the first nitroxide able to control the homopolymerization of MMA by NMP up to 80% conversion with good livingness under mild conditions. Unfortunately, due to high BDE(C–ON) for other alkyl fragments than tertiary alkyl fragments ($E_{a,d} = 126.0 \text{ kJ mol}^{-1}$ for **30**)⁹⁹ and the competition between the C–ON and the C–ON bond cleavage,¹⁰⁷ the NMP of olefins other than 1,1-disubstituted olefins was uncontrolled. The potential of aryl nitroxides as controlling agents was confirmed by other aryl nitroxides such as **31** and **32** prepared by the Grubbs group.^{146,147}

3.4 Proximal Bisnitroxides

There are two types of bisnitroxides: those attached by a long flexible linker behaving as two independent nitroxides (e.g., **34** promoted by the Braslau's group)^{148,149} and the proximal binitroxides for which the two nitroxide moieties are maintained close enough for the occurrence of spin–spin interaction (e.g., **33** promoted by the Rassat/Vairon groups).¹⁵⁰ These types of nitroxide appeared to be unstable^{149,150} at the temperatures required for NMP, which might also be an advantage for performing fast polymerization.⁴⁷ Rassat/Vairon and Kaim's groups¹⁵⁰ reported that the proximity of the two nitroxide moieties had no significant effect either on the C–ON bond homolysis or on the polymerization outputs, whereas Braslau's group¹⁴⁹ reported a slight difference for the k_d of the C–ON bond homolysis and for the polymerization.

4 ALKOXYAMINES AND THEIR KINETIC BEHAVIOR

The kinetic behavior of alkoxyamines involves the homolysis of the C–ON bond releasing alkyl radical and nitroxide, the cross-coupling (reformation) reaction between the nitroxide and the alkyl radical, the Cope-type elimination and intermolecular H-transfer reactions, the CO–N bond homolysis, as well as the stability of the nitroxide (Scheme 3). The occurrence and the rate constants of all these reactions depend on the structures of the nitroxide, the alkyl radical, and the nitroxyl and alkyl fragments.

4.1 Preparation of Alkoxyamines

The preparation of alkoxyamines has been reviewed by Bertin *et al.*,³⁶ Nesvabda,¹⁵¹ and Greene and Grubbs¹⁵² and will not be discussed hereafter. In most of the cases, the preparation of alkoxyamines is performed through (3) (Scheme 3) which corresponds to the cross-coupling reaction between a nitroxide and an alkyl radical. Thus, the main outcome is the generation of alkyl radicals. Nowadays, the most applied procedure is the atom transfer radical addition (Scheme 5a) as developed by Matyjaszewski *et al.*¹⁵³ *In situ* preparation of alkoxyamines has been reviewed by Detrembleur *et al.*⁶⁹

Guillaneuf *et al.*¹⁵⁴ reported the preparation of a highly labile and functionalized alkoxyamine using the photolytic cleavage of an azo compound or alkyldithiocarbamate below room temperature (Scheme 5b). In many cases, yields ranged from

Scheme 5 Different routes for preparing alkoxyamines: (a) by atom transfer radical addition (ATRA), and (b) by irradiation.

Scheme 6 Different routes for preparing alkoxyamines (a) oxidation/reduction/ β -fragmentation of aldehydes, and (b) decomposition of alkyl catechol boron compounds.

good to quantitative. The drawbacks of this procedure are the cage effect occurring at low temperature and depending on the solvent leading to the low efficiency of azo compounds, and the availability of azo or alkyldithiocarbamate compounds.

Schoenig *et al.*¹⁵⁵ developed a very versatile and mild procedure for preparing alkoxyamines based on the oxidation of an aldehyde and its reduction/ β -fragmentation in the presence of catalytic amount of CuCl into an alkyl radical which was scavenged by a nitroxide (Scheme 6a). Except for a few cases (4 over 27 examples), good to excellent yields were reported. One drawback of this procedure is the use of an excess of hydrogen peroxide, which sometimes may lead to the formation of instable organic peroxides that may induce hazardous decomposition during the workup when not enough care is taken.

A more specific procedure for the preparation of acrylate-based alkoxyamines relying on the decomposition of catecholboron enolates in the presence of nitroxide (here **2**) was proposed by the groups of Studer of Renaud (Scheme 6b).¹⁵⁶ Yields varied from moderate to excellent.

4.2 C–ON Bond Homolysis

4.2.1 Measurement of the C–ON Bond Homolysis Rate Constant k_d for Alkoxyamines

As mentioned above, the decay of an alkoxyamine is governed by the PRE (Scheme 1a) and an accurate and reliable determination of k_d requires

the suppression of the cross-coupling reaction (back reaction), which is achieved either by scavenging the alkyl radical or by reducing the nitroxide into hydroxylamine. Consequently, in the presence of an excess of scavengers/reductants, k_d is obtained either by EPR monitoring of the growth of the nitroxide signal^{7–9,27} or by NMR monitoring of the typical signal of an alkoxyamine,^{157,158} or by monitoring the size exclusion chromatography (SEC) traces of a macroalkoxyamine,¹⁵⁹ or by monitoring changes in the fluorescence¹⁶⁰ of a labeled nitroxide. The limitations of each method, as well as the meanings and the reliability of frequency factors, have been discussed by Bertin *et al.*³⁶

4.2.2 Alkyl Fragment

The first report about the dependence of k_d on the structure of the alkyl fragment was made by Kovtun *et al.*⁷ Soon after, Howard and Tait^{8,9} reported a study on a larger series of compounds. However, the first relationship was provided by Mulder *et al.*,¹⁶¹ who showed that the activation energy E_a for the C–ON bond homolysis, that is, $\log k_d$, increased with decreasing BDE of the C–H bond of the released alkyl radical, meaning that the alkoxyamine homolysis is partly governed by the stabilization of the released alkyl radical. A few years later, Marque *et al.*³⁶ reviewed the various effects of the structure of the alkyl fragment on k_d . They are summarized in Figure 7.

The anomeric effect,¹⁶² which leads to striking decrease in k_d , was first reported by Ciriano *et al.*¹⁶¹ for alkoxyamine carrying O and N atoms,

Figure 7 Various effects of the alkyl (a) and nitroxyl (b) fragments on the C-ON bond homolysis. [Reproduced from Ref. 45. © Royal Society of Chemistry, 2011.]

and for S atom and carbonyl group by Marque *et al.*¹⁶³ The steric effect, leading to an increase in k_d , is due to the size of R₁, R₂, and X groups and destabilizes the reactant.¹⁶⁴ The stabilization of the alkyl radical decreases the energy of transition state (TS) leading to an increase in k_d . As described by Pauling, the bond is composed of an enthalpic term and a polar term, that is, the difference ($\chi_O - \chi_C$)²,^{165,166} thus, a decrease in the difference in electronegativity χ between the carbon and oxygen atoms of the C-ON bond destabilizes the initial state, leading to an increase in k_d .¹⁶⁴ The anchimeric effect was probably observed for the first time with pyridyl and thiopyrrole groups carried by **2**-based alkoxyamines by Marque *et al.*¹⁶³ and proved for **14**-based alkoxyamines.¹⁶⁷ This effect destabilizes the initial state by donation of a lone pair of the heteroatom to the antibonding orbital of the C-ON bond, $n_X \rightarrow \sigma^*_{C-ON}$, leading to an increase in k_d . The remote polar effect was reported by Marque *et al.*^{168,169} for several series of **14**-based alkoxyamines as well as for a few examples of other types of alkoxyamines.⁵⁰ This effect plays the same role as the polar effect, that is,

it destabilizes the initial state leading to an increase in k_d . It must be noted that all the effects mentioned above are general to any type of alkoxyamine. On the other hand, the remote steric effect has only been observed for **14**-based alkoxyamines.¹⁷⁰ This effect probably involves some hindered rotations to reach TS from the initial state, leading to the destabilization of TS, and hence, to a decrease in k_d .

The two large series of alkyl fragments available for **2**- and **14**-based alkoxyamines gave the opportunity to develop structure–reactivity relationships describing the impact of the three main effects—stabilization (σ_{RS}), polar (σ_I), and steric (ν)—on k_d , as given by (23) and (24), respectively¹⁶⁴:

$$\log(k_d/s^{-1}) = -14.80 + 13.90 \times \sigma_{RS} + 13.60 \times \sigma_I + 6.60 \times \nu \quad (23)$$

$$\log(k_d/s^{-1}) = -14.33 + 15.30 \times \sigma_{RS} + 19.5 \times \sigma_I + 7.00 \times \nu \quad (24)$$

4.2.3 Nitroxide Fragment

Rizzardo and Moad were the first to report that k_d increased with the congestion around the nitroxyl moiety of the alkoxyamine.¹³ A few years later, Marque¹⁷¹ proposed a structure–reactivity relationship (25) for almost all types of nitroxyl fragments (except for aryl nitroxides) describing the impact of the ring size, the congestion around the nitroxyl moiety, the substitution on the ring, the presence of an H atom in position β , and the polar and the stabilization effects. First four effects were described by the Taft-type steric constants E_s , and, as the polar and stabilization effects were aliased, the Hammett polar constant σ_L was applied.

$$\log(k_d/s^{-1}) = -5.73 - 2.81 \times \sigma_L - 0.83 \times E_s \quad (25)$$

Several trends were observed as follows³⁶:

- The increase in k_d due to the release of steric strain which is due either to the relief of the ring strain, that is, increase in the $\langle \text{CNC} \rangle$ valence angle which in turn increases the congestion around the nitroxyl moiety, from 5- to 7-membered rings^{13,137,171,172} or to the change in hybridization of sp^2 to sp^3 of one of the atoms on the 7- or 8-membered ring.¹³⁷
- The increase in k_d due to the increase in the bulkiness of groups flanking the nitroxyl moiety, that is, increase in the congestion.^{13,36,83,138,164,165,172} However, this increase can be balanced by the leveled steric effect¹⁷³ (*vide infra*).^{36,171,174–176}
- The increase in k_d due to the presence of a substituent on the ring, which limits the number of possible conformations, that is, fewer conformations to “freeze” in TS and, hence, higher activation entropy $\Delta S^\ddagger$. However, this substituent effect depends on the position and the size of the ring.³⁶
- The increase in k_d due to the presence of intramolecular hydrogen bonding (IHB) which stabilizes the generated nitroxide, and, hence, lowers the energy of TS.^{163,172,177–179}
- The decrease in k_d with increasing electron-withdrawing capacity of the groups attached to the nitroxyl moiety (polar effect) which destabilizes the nitroxide and, hence, destabilizes TS.^{171,172}

- The decrease in k_d due to the entropic effect which increases with the size of the ring and depends on the substituents and their positions on the ring.^{36,172}

Interestingly, those effects are spread in enthalpic term—congestion around the nitroxyl moiety and relief of the ring strain (steric effect), IHB, polar effect—and entropic term—substituent effect, ring size, hybridization of the atom of the ring.

The leveled steric effect has been proved^{36,171,172} and invoked^{171,174} to include the noncyclic nitroxyl fragments into (25). However, results provided by Studer *et al.*¹⁷⁶ proved that the steric effect and strain relief are less obvious than described by (25), even though (25) provides often accurate and reliable k_d values for noncyclic nitroxyl fragments. Consequently, the data estimated for noncyclic nitroxyl fragments by (25) should be handled with caution.

4.3 C–ON Bond Reformation

A thorough survey discussing the methods of measurement of k_c , the Arrhenius parameters, the factors ruling the reformation reaction depending on the structures of both the nitroxides and the alkyl radicals, as well as a large collection of k_c values, is provided by Bagryanskaya *et al.* (E. G. Bagryanskaya and S. R. A. Marque, *Chem. Rev.* in preparation).

4.3.1 Measurement of the C–ON Bond Reformation Rate Constants k_c of Alkoxyamines

Laser flash photolysis-kinetic absorption spectroscopy (LFP-KAS) is the most popular and suitable technique to measure k_c values for the formation of unimolecular species. Several methods have been developed aiming to overcome the low absorption of some alkyl radicals and the difficulties in preparing suitable initiators. The kinetic analysis of the NMP experiment⁸² (26) and the radical nitroxide recombination-pulsed lamp photolysis-size exclusion chromatography¹⁸⁰ (RNR-PLP-SEC) are the only approaches and techniques available to estimate $k_{c,ds}$ values for polymeric radicals. Amazingly, many k_c values exhibit a reverted behavior with the

temperature, that is, k_c decreases with increasing temperature.¹⁸¹ Moreover, for many cases, k_c values also exhibit very weak temperature dependence, that is, k_c at 120 °C differs by less than a factor two from k_c given at room temperature.¹⁸¹ Those unexpected behaviors, due to an entropic effect, have been thoroughly discussed by Fischer *et al.*¹⁸¹

$$\ln \frac{[\text{monomer}]}{[\text{monomer}]_0} = \frac{3}{2} k_p \left(\frac{k_{d,ds}}{3k_{c,ds}} \times \frac{[\text{initiator}]_0}{k_{t,ds}} \right)^{1/3} \times t^{2/3} \quad (26)$$

4.3.2 Alkyl Fragment

Bowry and Ingold¹⁸² were the first to present a $\log k_c$ versus BDE(C–H) correlation and showed that the increase in the stabilization (enthalpic effect) of the alkyl radical led to a decrease in k_c . In a recent survey, Bagryanskay *et al.* applied a multiparameter analysis— σ_{RS} for the radical stabilization, σ_I for the polarity, and ν for the bulkiness at the radical center—to five nitroxides, **2**, **14**, **27**, **28**, and **35**, as given in (27) for **14**:

$$\begin{aligned} \log(k_c/l \times \text{mol}^{-1} \times \text{s}^{-1}) \\ = 10.72 - 6.72 \times \sigma_{RS} + 14.24 \times \sigma_I - 2.89 \times \nu \end{aligned} \quad (27)$$

Several of the following trends arose (Figure 8):

- k_c decreased with increasing stabilization, due to poor overlap of the singly occupied molecular orbitals (SOMO) of the nitroxide and alkyl radical at the TS. Furthermore, the impact of this effect increased with the bulkiness around the nitroxide moiety.
- k_c decreased with increasing bulkiness of the alkyl radical, which hampers the approach to the radical center.
- k_c increased with increasing polarity, which is related here to the change of sp^2 hybridization at initial state to partly pyramidalized sp^3 -type orbital at the TS. In general, an electron with drawing groups (EWG) attached to the radical center favors its pyramidalization.

Figure 8 Different effects on k_c due to the structures of the nitroxide and alkyl radical. [Reproduced from Ref. 45. © Royal Society of Chemistry, 2011.]

Although they were investigated for the C–ON bond homolysis, the anomeric, anchimeric, remote steric, and polar effects were not investigated for the C–ON bond reformation because the initiators for the corresponding alkyl radicals were not available.

4.3.3 Nitroxide Fragment

Although k_c values were known for several types of nitroxides,^{181–184} Marqu $\acute{e}$ *et al.*^{185–187} were the first to report multiparameter analysis— σ_I for the stabilization/polarity (it was assumed that the polarity and stabilization effects were aliased and exhibiting the same trend), and E_s for the steric effects—for several alkyl radicals such as **3**, **20**, **21**, **36**, and **37**. A typical correlation is given as in (28) for **20**:¹⁸⁷

$$\begin{aligned} \log(k_c/l \times \text{mol}^{-1} \times \text{s}^{-1}) \\ = 10.07 + 0.52 \times \sigma_I + 0.45 \times E_s \end{aligned} \quad (28)$$

Several of the following trends arose (Figure 8):

- k_c decreased with increasing bulkiness of the group flanking the nitroxyl moiety.¹⁸⁵ However, the impact of this effect depended on the delocalization of the odd electron on the alkyl radical.
- k_c increased with the presence of an EWG attached to the nitroxyl moiety (polar effect).¹⁸⁶ However, the impact of this effect depended on the delocalization of the odd electron on the alkyl radical.
- The ring size, the hybridization of the atoms of the ring, the presence of substituents at other

positions than the positions α to the nitroxyl moiety had no influence.

IHB was investigated for **38** and no significant differences were observed.¹⁸¹

4.4 Side-Reactions

Although these side-reactions are crucial for the fate of NMP and their effects on NMP very much depends on the extent of their occurrence, they were not as carefully and intensively investigated as the C–ON bond homolysis and reformation.

4.4.1 CO–N Bond Homolysis

This reaction has been little investigated because it generally occurs for alkoxyamines exhibiting C–ON bond enthalpies higher than 140 kJ mol^{-1} ,^{13,26,140} whereas only alkoxyamines with BDE(C–ON) lower than 140 kJ mol^{-1} are interesting for NMP.^{20,24,26} However, Gimes *et al.*¹⁰⁷ observed CO–N bond homolysis for **26**-based alkoxyamines with BDE(C–ON) around 126 kJ mol^{-1} .⁹⁹ Furthermore, this side-reaction is likely to play a role in the nonoccurrence of the intermolecular H-transfer reaction.⁴⁷

4.4.2 Nitroxide Stability

The nitroxide stabilities have been investigated over the last 6 decades.^{188–192} There are two types of stability: the intrinsic stability which depends only on the molecular structure of the nitroxide, and the stability to reactants which depends on the structure of both the nitroxide and the reactant.

The intrinsic stability is related to three types of side-reactions as follows:

- the disproportionation reaction requiring the presence of at least one hydrogen atom in position β , and leading to the subsequent hydroxylamine and nitron;
- the α -fragmentation reaction leading to a nitroso compound and a radical species;

- the β -fragmentation reaction leading to a nitron and a radical species.

The occurrence of these fragmentation reactions depends on the bulkiness of the groups attached to the nitroxyl moiety, the stabilization of the released radical, and the thermodynamic stability of the diamagnetic compounds. Nilsen and Braslau¹⁹² carefully investigated the decomposition of **16** and showed that the main decay pathways were the fragmentation reactions. Marque *et al.*¹⁴⁰ investigated the kinetic stability of several nitroxides and showed that $t_{1/2}$ spanned from several hours to 20 minutes at 120°C and depended dramatically on the structure of the nitroxide and the experimental conditions.

The stability toward reactants relies on both the congestion around the nitroxyl moiety, which hampers the approach of the H-atom donors such as thiol, phenols, metal hydrides,¹⁵⁷ and the redox potential of nitroxide controlling the reaction with reductant/oxidant such as sodium ascorbate.¹⁹³

4.4.3 H-Transfer Reaction and Cope-Type Elimination

As mentioned above, the occurrence of reactions affording hydroxylamine and alkene is crucial for the fate of NMP. These side-products are generated by the intermolecular H-transfer reaction between the nitroxide and the alkyl radical and/or the Cope-type elimination. Such reactions were investigated for phenylethyl radical **20** and homologs,^{85,96,105,194} alkoxy-carbonyl-ethyl radical,^{85,97,105} and alkoxy-carbonyl-2-prop-2-yl radical.^{51,85,97,99,105} It was shown for the cross-coupling between nitroxide and phenylethyl radical that the intermolecular H-transfer reaction is a minor event which does not impede the success of the NMP. For the two other radicals, these reactions can occur to large extent, spoiling the NMP.

Edeleva *et al.*^{51,99} provided a very simple and efficient procedure allowing discrimination between these two processes (Scheme 7):

- when the experiment is performed under scavenging conditions (k_{PhSH}) which completely and efficiently suppress the cross-coupling reaction k_c , any detected alkene is only due to the occurrence of the Cope-type elimination;

Scheme 7 Reactions occurring during the thermolysis of an alkoxyamine under various conditions.

- when the experiment is performed under PRE conditions, the detected alkene is generated by both processes. As the Cope-type elimination does depend on the procedure, each rate constant k_d , k_{cD} , and k_{dD} is readily determined.

Even though these side-reactions have been investigated for the decay of two series of alkoxyamines,^{51,97} no clear trends have emerged, and these events still look as if they occur randomly, for example, a large amount of alkene is observed for **22**⁸⁵ whereas no alkene is observed for **39** and **11**,¹⁰⁴ any is observed for **30**,⁹⁹ and a very small amount (<5%) is observed for **40**, and **41**.⁸⁷ Furthermore, their observation very much depends on the experimental conditions, that is, they were not detected by room temperature chemically induced dynamic nuclear polarization (CIDNP)^{186,195} but detected by high-temperature CIDNP,¹⁹⁶ and detected for **42** but not for **25**, because of the instability of the nitroxide and good kinetic circumstances,⁵¹ or because of the cancellation due to the presence of an acid as exemplified by **12**.

Indeed, the occurrence of these reactions is controlled by the following requirements of the TS:

- The intermolecular H-transfer reaction requires a linear TS, that is, the $\langle \text{NO}^\bullet \cdots \text{H}-\text{C} \rangle$ angle must be as close as possible to 180° .
- The Cope-type elimination requires a 5-membered cyclic TS exhibiting an $\langle \text{N}^\bullet \cdots \text{H}-\text{C} \rangle$ angle as close as possible to 150° .

Thus, predicting the occurrence of these reactions requires thorough calculations aiming to determine the accurate requirements for TS and how they are related to the molecular structures of products and starting materials.

4.5 Miscellaneous

4.5.1 Penultimate Unit Effect

The PUE for the C-ON bond homolysis has been little investigated because of the tedious work needed to prepare the starting alkoxyamines. Using 1,2-addition of radical onto alkene and the scavenging of the subsequent alkyl radical by **14**,³⁸ several models suitable for investigation were prepared.¹⁹⁷ It was shown that (24) developed for simple alkoxyamine models based on **14** holds for subsequent alkoxyamines carrying a penultimate fragment.¹⁹⁷ It was also shown that the PUE spans from weak (1.5-fold), from **18** to **43**, to strong (18-fold) from **18** to **44**.¹⁹⁷ Thus, some clear trends were drawn as follows:

- for the diads $\text{YCH}_2\text{CH}_2\text{MeZC-}$, $\text{YMeCHCH}_2\text{MeZC-}$, $\text{YCH}_2\text{CH}_2\text{ZHC-}$, and $\text{YMeCHCH}_2\text{ZH}_2\text{C-}$ only very weak PUE was reported;
- for the diad $\text{YMe}_2\text{CCH}_2\text{ZHC-}$, strong PUE was reported;
- for the diad $\text{YMe}_2\text{CH}_2\text{ZMeC-}$, very strong PUE is expected from (24)¹⁹⁷;

- for the triad $\text{YMe}_2\text{CCH}_2\text{ZHCCH}_2\text{ZHC-}$, no effect of the antepenultimate unit was observed;
- the PUE depends on the nitroxyl fragment, for example, no PUE for **43**¹⁹⁷ was detected, whereas clear PUE was detected for **45**¹⁵⁷;
- the importance of the PUE depends on the configuration of chiral carbons, as exemplified with **45**.¹⁵⁷

The PUE for C–ON bond reformation has been even less investigated than for the C–ON bond homolysis, because no suitable radical initiators were available. Developing a new procedure of k_c measurements, Lallevee *et al.*¹⁸⁴ were able to measure the PUE for a few dyads $\text{YMeHCH}_2\text{CHZ-}$ and $\text{YMeHCH}_2\text{CMeZ-}$. No significant differences have been observed as compared with the unimolecular models.

4.5.2 Chain Length Effect

The effect of the chain length on the C–ON bond homolysis rate constant has mainly been investigated for three nitroxyl fragments: **2**, **14**, and **28**. As mentioned above, Fukuda *et al.*¹⁹⁸ and Bon *et al.*¹⁹⁹ reported different values for the k_d of **9**, nicely accounted for by the PUE, compare to the model alkoxyamine **17**. Gnagnou *et al.*,⁸² Bertin *et al.*,⁹¹ and Goto and Fukuda⁴⁶ reported a roughly twofold increase in $k_{d,ds}$ for **46** compared to **18**.¹⁴⁰ Goto and Fukuda⁴⁶ reported $k_{d,ds}$ values for **47** similar to those¹⁴⁰ observed for **48**. On the other hand, for **49**, Marque *et al.*⁹⁰ reported a linear increase of $k_{d,ds}$ with the molecular mass M_n . Nonetheless, except for **49**, the effect of the chain length is weak and well accounted for by the PUE. For **49**, this chain length effect is likely due to the remote polar effect.

The effect of the chain length on the C–ON bond reformation rate constant $k_{c,ds}$ has not received as much interest as that on $k_{d,ds}$ because the required radical initiators were not available. Most values came from the kinetic analysis of the polymerization, providing that reliable k_d , k_p , and k_t values were available, providing that the system monitored complied with the requirements that the equations used held, and providing that side-reactions were minor on the experimental time. Although for most cases, the reported $k_{c,ds}$ were reliable, the

k_c for the unimolecular species were not measured, forbidding any comparison. To overcome these drawbacks, Guillaneuf *et al.*¹⁸⁰ developed a new procedure and applied it to the measurement of $k_{c,ds}$ for **50** with **2** ($k_{c,ds} = 1.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) and **14** ($k_{c,ds} \approx 2 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$), and for **51** with **14** ($k_{c,ds} = 6 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$)⁸⁶ and **26**¹⁰⁶ ($k_{c,ds} = 1.4 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$). Consequently, the $k_{c,ds}$ reported for **9**^{23,180} (**52**,¹⁷⁸ **53**,⁴¹ and **54**¹⁷⁸) are of the same order of magnitude as for the unimolecular model.^{181,184} The $k_{c,ds}$ values reported for **46**,^{142,180} **49**,²⁰⁰ and **55**¹⁰⁶ are roughly one order of magnitude smaller than those reported for the unimolecular species.^{181,184} The $k_{c,ds}$ values reported for **56**⁸⁶ are roughly two orders of magnitude lower than those reported for the unimolecular species.^{181,184}

These few $k_{c,ds}$ values span over two orders of magnitude and depends dramatically on the molecular structure of the nitroxide and on the type of polymeric radical, in a such way that they cannot be predicted. Such a variation will play an important role in the fate of NMP.

4.5.3 Solvent Effect

For the C–ON bond homolysis, the solvent effect was investigated for two series^{13,90} and only a weak influence was reported, that is, a twofold increase for increasing solvent polarity from hexane to alcoholic solvents.¹⁶³ Interestingly, **13a–e** were reported to be soluble almost in any solvent from pentane to water.²⁰¹

For the C–ON bond reformation, the solvent effect was thoroughly investigated by Ingold *et al.*²⁰² who showed that k_c was decreased with the increasing polarity and viscosity of the solvent.

4.5.4 Acid and Salt Effects

Georges *et al.*²⁰³ and Marque *et al.*¹⁶³ showed that k_d was not modified by the presence of an acid but the later removed the nitroxide, and thus modified the kinetic behavior of NMP. However, these investigations were performed on an alkoxyamine without protonable functions close to the CON moiety. Under harsh conditions, Mazarin *et al.*²⁰⁴ showed that a **14**-based alkoxyamine was protonated and the C–ON bond was strikingly strengthened.

On the other hand, Bagryanskaya *et al.* reported a 10-times lower k_d value for the protonated form **57** than for the nonprotonated form **58**.²⁰⁵ Moreover, Brémond *et al.* reported a 15-fold increase in k_d for **59** upon protonation of the leaving alkyl radical of **60**.²⁰⁶

Marque *et al.* investigated the salt effect with **13a–d** alkoxyamines, and noted only a minor effect for one diastereoisomer.²⁰¹

Scaiano *et al.*²⁰⁷ reported a very weak (twofold decrease) effect of the acidic conditions on k_c for the cross-coupling reaction between **2** and **36**. On the other hand, Bagryanskaya *et al.* reported a two times increase in k_c for the cross-coupling reaction of **61** with **37** upon protonation of **62**.²⁰⁵

4.6 Calculations

At the earlier stage of NMP, BDEs of alkoxyamines had been investigated using semiempirical and low cost methods.^{13,208–210} This provided good trends but the energies were not reliable and not accurate enough to investigate subtle effects. Thus, only calculations performed with methods using at least DFT will be discussed hereafter.

4.6.1 C–ON and CO–N Bond Dissociation Energies

As early as 1999, Marsal *et al.* showed that DFT afforded reliable BDE values for simple alkoxyamines in a reasonable time.²¹¹ With a large set of data, Coote *et al.* showed that, in general, the G3(MP2)-RAD method afforded better results than the DFT methods.²¹² They showed that BDE(CO–N) were not correlated to the BDE(C–ON). They noted that CO–N bond homolysis (unwanted reaction, Scheme 8, route a) is favored over the C–ON bond homolysis (Scheme 8, route b) when the aminyl radical generated is strongly stabilized.

Scheme 8 The two possible fragmentations of the C–O–N bond sequence.

4.6.2 Correlations

The analysis of k_d and k_c using a computational approach did not raise strong interest. However, as soon as in 1998, Iwao *et al.*²¹³ showed the suitability of calculations to describe steric and stabilization effects involved in the change in k_c . Some studies reported the correlation between k_d and BDE.¹⁶² Coote *et al.*²¹⁴ showed that computational tools are suitable to develop correlations both with k_d and k_c based on calculated parameters, and are able to describe the effects involved in the C–ON bond homolysis as it was done using empirical Hammett, Taft, and Charton parameters. Both experiments and computational approaches are in good agreement.

4.6.3 Miscellaneous

Calculations appeared to be very valuable to investigate anomeric,¹⁶² anchimeric,¹⁶⁷ remote steric,¹⁷⁰ and salt effects.²⁰¹ Indeed, they highlighted the $n \rightarrow \sigma^*$ interaction of the (N)O lone pair of oxygen to the antibonding orbital of the C–O(COME) bond (Figure 9a), which dramatically increases the strength of the C–ON bond in **63**.¹⁶² Calculations allowed the determination of the difference in k_d between the diastereoisomers of **11** due to the $n \rightarrow \sigma^*$ interaction of the (CO)OR lone pair of oxygen to the antibonding orbital of the C–O(N) bond (Figure 9b).¹⁶⁷ It was also of invaluable help to determine the origin of the effect of the penultimate unit for the diastereoisomers of **45**.²¹⁵

4.6.4 Reaction Pathway

As it is difficult to locate the TS of homolysis, no attempts were made to investigate the TS of the C–ON bond homolysis in alkoxyamines. On the other hand, few investigations on the TS of the cross-coupling reaction and the intermolecular H-transfer reaction were performed.^{216–218} Braslau *et al.*²¹⁶ investigated the cross-coupling reaction of some model reactions using DFT methods but did not find any TS. However, they noted that the angle between the alkyl radical and the nitroxide was around 110–120°, values close to that observed in the final alkoxyamine. A few years later, Kaim and Megiel^{217,218} investigated both the

Figure 9 (a) Anomeric effect $n_O \rightarrow \sigma^*_{O-C}$. (b) Anchimeric effect $n_O \rightarrow \sigma^*_{C-ON}$. [(a) Reproduced from Ref. 162. © Wiley-VCH Verlag GmbH & Co. KGaA, 2006. (b) Reproduced from Ref. 167. © Wiley-VCH Verlag GmbH & Co. KGaA, 2006.]

cross-coupling reaction and the H-transfer reaction between TEMPO and homologs of radicals **20** and **64**. Using a lower method, they were able to locate TS for the cross-coupling reaction exhibiting the same features as reported by Braslau *et al.* They were also able to determine TS for the H-transfer reaction, except that the value of the C-H...O(N) angle (around 105°) is much smaller than the one conventionally accepted for intermolecular H-transfer (around 180°).

Nevertheless, these data provide some information about the structure of the activated complex at TS. For the homolysis of the C-ON bond (Figure 10a), a few requirements are expected:

- lengthening of the C-ON bond and shortening of the CO-N bond;

- flattening at the nitrogen and carbon atoms of the CON sequence, that is, changing from sp^3 hybridization to sp^2 hybridization;
- a dihedral $\langle OC \text{ insaturation} \rangle$ angle close to 90° .

These geometrical changes lead to interactions favoring the homolysis such as:

- $n_N \rightarrow \sigma^*_{O-C}$ interaction between the nitrogen lone pair and the antibonding orbital σ^* of the O-C cleaved bond;
- $\sigma_{O-C} \rightarrow \pi^*_{\text{insaturation}}$ interaction between the (N)O-C bonding orbital σ (nascent SOMO of the alkyl radical) and the antibonding orbital π^* of the insaturation bond to the nascent radical center.

Any other interactions occurring may either strengthen or weaken the C-ON bond (*vide supra*). As homolysis and reformation reactions of the C-ON bond share the same TS, for the reformation reaction converse requirements are expected (Figure 10b), namely:

- shortening of the $C \cdots ON$ distance and lengthening of the O-N bond;
- pyramidalization at the nitrogen and carbon atoms of the CON sequence, that is, changing from sp^2 hybridization to sp^3 hybridization.

These geometrical changes lead to interactions favoring the reformation of the C-O bond such as:

- $SOMO_C \rightarrow \pi^*_{O-N}$ interaction between the SOMO of the alkyl radical and the antibonding orbital π^* of the nitroxide, that is, its SOMO.

Figure 10 Expected interactions at TS for (a) the C-ON bond homolysis, and (b) for the cross-coupling reaction between nitroxide and alkyl radical.

5 POLYMERIZATION

NMP has been employed for the preparation of a large range of macromolecular architectures (Figure 11) and compositions allowing a fine tuning of their physico-chemical properties.

5.1 Homopolymerization

NMP of styrene and styrene-based monomers such as styrenes para-substituted with F, Cl, Br, CH₃, OCH₃, CF₃, CH₂Cl, 4-acetoxystyrene, 4-*tert*-butoxystyrene, or even *para*-(1-methylcyclohexyloxy)styrene has been successfully achieved.^{219,220} A large number of nitroxides including both cyclic such as **TEMPO**^{179,221–223} and its derivatives and non-cyclic ones such as di-*tert*-butyl-*N*-oxyl (**DBNO**),⁴⁰ **TIPNO**,^{41,142} and **SG1**^{82,142} were tested leading efficiently to precisely controlled polymer chains in terms of molar mass, PDI, and chain-end functionality.

TEMPO^{224–231} and **SG1**-mediated^{232,233} radical polymerizations were also successfully applied to vinylpyridine derivatives.

Owing to their particular high propagation rate constants, the NMP of acrylic esters is only achievable with sterically hindered analogs^{174,222} or with acyclic nitroxides such as **SG1**^{56,229,234} and **TIPNO**^{227,235,236} derivatives. It has to be mentioned that the best results were obtained with the development of the highly labile **SG1**-based alkoxyamines allowing an almost ideal building up of the PRE.⁴⁹

NMP of acrylic esters is now well established and applied with efficacy to a wide range of acrylic esters (*n*-butyl acrylate (BA), *tert*-butyl acrylate, 2-hydroxyethyl acrylate,²³⁷ *N*-acryloylmorpholine,²³⁸ 2-hydroxypropyl acrylate,²³⁹ 1,1,2,2-tetrahydroperfluorodecyl acrylate,

-(acryloyloxy)ethylbenzyltrimethylammonium chloride,²⁴⁰ 2-(dimethylamino)ethyl acrylate,^{241,242} trimethylsilyl propargyl acrylate,²⁴³ etc.) leading to well-controlled molar masses and high livingness.

Acrylonitrile and Acrylic Acid

The controlled homopolymerization initiated by a **TIPNO**-based alkoxyamine showed good control until high-molar masses.⁴¹ A deep investigation on polybutylacrylate-*b*-polyacrylonitrile (PBA-*b*-PAN) copolymer made with **SG1** by NMP showed that the use of PAN macroalkoxyamine to *n*-BA was less efficient than that from PBA macroalkoxyamine to acrylonitrile (AN) suggesting some difficulties to control AN properly in the presence of **SG1**.²⁴⁴

NMP of acrylic acid was performed in 1,4-dioxane solution at 120 °C in the presence of **SG1**-based alkoxyamine. However, the results showed a good control over the polymerization only when moderate molar mass polymers were targeted.^{245,246}

Acrylamide, *N*-Substituted, and *N,N*-Disubstituted Acrylamides

As for the *N*-substituted acrylamides, NMP has been used for the controlled polymerization of *N*-isopropylacrylamide (NIPAAm),²⁴⁷ *tert*-butylacrylamide,²³⁹ *N,N*-dimethylacrylamide (DMAAm),^{232,238,240,248–252} and *N,N*-diethylacrylamide (DEAAm).²³³

Dienes

NMP of butadiene and of isoprene in the presence of **TEMPO** was studied by Georges²⁵³ and Boutevin,^{254,255} respectively. Efficient controlled radical polymerization of butadiene and of isoprene was also demonstrated in the presence of **TIPNO**^{256–258} and more recently on isoprene with both **TEMPO** and **4-oxo-TEMPO 65**.²⁵⁹

Figure 11 Some examples of the various polymer structures achievable by NMP.

Methacrylic Esters

Polyalkylmethacrylates represent an important class of material covering a broad range of applications. Therefore, many efforts have been focused on the NMP polymerization of alkyl methacrylate and more specifically MMA. A successful NMP of MMA has been a difficult achievement, mainly, owing to two different reasons closely related to the nature of the nitroxide used. For instance, it is assumed that NMP of MMA with **TEMPO** fails because of the occurrence of an undesired hydrogen atom abstraction from the nitroxide onto the propagating radical PMMA chain end to form the corresponding saturated polymer chain end and hydroxylamine.^{85,88,133,260} With **SG1**, the uncontrolled nature of MMA polymerization has been attributed to the too large activation–deactivation equilibrium constant which impedes a good quality of control and livingness.⁸⁶ In the case of high K_{eq} (12), the **SG1** acts as a spectator, therefore, the concentration of propagating alkyl radical is high enough to lead to a significant proportion of irreversible disproportionation reactions resulting in the loss of the control. The irreversible termination reactions mentioned above result directly in an accumulation of the stable **SG1** nitroxide in the sample. Obviously, at a given concentration, the **SG1** slows down dramatically the polymerization of MMA by reversible termination reaction with the propagating radical chains. When the concentration of **SG1** is too high, Charleux and coworkers detected the occurrence of both cross-disproportionation and bimolecular termination in **SG1**-mediated MMA polymerizations.⁸⁷

Up to now, several successful strategies have been developed to control the polymerization of methacrylate. Detrembleur *et al.*⁶⁹ demonstrated that the bulk polymerization of MMA and *tert*-butyl methacrylate (*t*BMA) conducted in the presence of methyl 2-methyl-3-nitro-2-nitrosopropionate (NMMA) was controlled when initiated by AIBN at 60 °C or using a mixture of NO/NO₂ mixtures. It has to be mentioned that this process, based on the *in situ* NMP, is intrinsically complex because several species are formed *in situ* as a result of the addition of both the initiating radicals and the propagating radicals. However, even if the polymerization control was not ideal (increase of the PDI along with increase of conversion), some encouraging results were obtained.

As mentioned earlier in this article, an alternative route consists in the copolymerization of a small percentage of a comonomer (styrene, acrylonitrile (4.4–8.8 mol%) with methacrylate to form not pure PMMA but PMMA-rich copolymers with low PDIs. In this case, it has been demonstrated that the K (12)) was increased positively, thanks to the presence of the comonomer used.^{89,261}

Regarding the control of the homopolymerization of MMA in the presence of nitroxide, the most successful route has been the use of *N*-arylnitroxides. It is thought that these nitroxides allow radical delocalization through the *N*-aryl moiety that could prevent the cross-disproportionation side-reaction, exhibit the proper kinetic parameters, and therefore allowing better control over MMA polymerization. For instance, it has been shown that the use of 2,2-diphenyl-3-phenylimino-2,3-dihydroindol-1-ylloxyl (DPAIO)-based alkoxyamines¹⁰⁶ and more recently *N*-phenyl nitroxide synthesized by *in situ* addition of carbon-centered radicals across the double bond of nitrosobenzene¹⁴⁶ or *N*-phenylalkoxyamine *N*-(1-methyl-(1-(4-nitrophenoxy)carbonyl)ethoxy)-*N*-(1-methyl-(1-(4-nitrophenoxy)carbonyl)ethyl) benzenamine¹⁴⁷ **66** allowed the NMP of MMA up to moderate conversions (50%). Unfortunately, even if some chain extension from the resulting PMMA macroinitiators has been achieved, the control of the polymerization of the second block was poor. This result suggests that the kinetic parameters of the macroalkoxyamines formed during the polymerization are only suitable for the MMA. Therefore, the NMP of methacrylates is still not completely achieved since more investigations are needed to find a nitroxide or a strategy to control efficiently styrenics, acrylate, and methacrylates and therefore to prepare in a convenient way, a wide range of tailor-made block copolymers.

Cyclic Ketene Acetals

Degradable aliphatic polyesters are receiving great attention. In this context, radical ring opening polymerization (ROP) turns out to be a very convenient and appealing technique to prepare such aliphatic polyesters.^{262,263} It has to be mentioned that 2-methylene-1,3-dioxepane was polymerized in the presence of **TEMPO**/di-*tert*-butyl peroxide at 125 °C.²⁶⁴

5.2 Random and Block Copolymerization

Living Random and Gradient Copolymers

Regarding the preparation of random or gradient copolymers, typically the same or very similar polymerization behaviors are observed when using either a conventional radical polymerization, or an NMP technique.^{112,265} The copolymers obtained when using the NMP technique exhibit very close compositions with obviously narrower PDIs.

A very interesting application of copolymerization consists in the control of various methacrylate derivatives^{89, 114–116, 118} using low amounts of comonomer such as styrene or acrylonitrile.²⁶¹

5.3 Polymerizations in Aqueous Dispersed Media

Radical polymerization can be conducted in various dispersed media,^{76,266,267} for example, emulsion, miniemulsion, microemulsion, precipitation, dispersion, and suspension. The continuous phase is usually water, but some examples also report the use of supercritical dioxide (scCO₂).^{268–277}

5.3.1 Aqueous Miniemulsion Polymerization

In miniemulsion system, monomer droplets are converted into polymer particles as the polymerization proceeds, and therefore, the transport of nitroxide or low molecular weight alkoxyamine in between the monomer droplets and the polymer particles in the aqueous phase (as in an *ab initio* emulsion polymerization) is not of any concern. Miniemulsion NMP can be broadly divided into two categories: (i) aqueous phase initiation and (ii) oil phase initiation. In general, miniemulsion polymerization requires the addition of a hydrophobe, such as hexadecane, to suppress Ostwald ripening.^{278,279} Interestingly, a nitroxide-terminated macroinitiator (for instance polystyryl-TEMPO) can be used instead of hexadecane.^{280,281} The addition of a small amount of high-molar mass polymers enhances droplet nucleation and stabilization.²⁸²

Typically, both oil- and water-soluble initiators have been investigated in miniemulsion NMP in the presence of TEMPO and SG1 nitroxides. Bicomponent systems were the first to be applied but improved systems were achieved using SG1-based water-soluble alkoxyamines.⁵⁹

5.3.2 Aqueous Emulsion Polymerization

Implementation of NMP in emulsion has proved to be a significant challenge. The main problems associated to this system were colloidal stability and high control/livingness. Indeed, to obtain successful emulsion NMP, several criteria have to be fulfilled. Typically, emulsion polymerization mainly involves large droplets (<1 μm) of hydrophobic monomer(s) and a large number of monomer-swollen micelles.²⁸³ Successful emulsion NMP implies that the polymerization takes place within small monomer droplets generated via diffusion of the monomer droplets through the aqueous phase. In contrast to miniemulsion, emulsion process requires the use of water-soluble radical initiators. Moreover, in order to ensure good control of the polymerization, the partitioning of nitroxide between the organic and aqueous phases allows the nitroxide concentration in the particles to be sufficiently high.

6 MACROMOLECULAR ADVANCED ARCHITECTURE AND COMPOSITIONS

6.1 Chain-End Functionalized Polymers from NMP

Various examples of α - and ω -functionalized polymers made from NMP have already been reported.²⁸⁴ Usually, α functionalization is obtained through the use of the corresponding functionalized alkoxyamine while ω functionalization is achieved after chemical transformation of the nitroxide moiety attached to the polymer chain end (Figure 12).

It has to be mentioned that the synthesis of functional polymers is the subject of intense research. Indeed a functional polymer exhibits specific properties valuable for the material application or in macromolecular engineering. The easiness of preparation of α,ω -functionalized polymers

Figure 12 Possible routes for α and ω functionalization.

is strongly related to the polymerization technique used. α -Functionalization of the polymer chains is obtained by using the commercially available or beforehand prepared initiator. ω -Functionalization is by far more difficult to obtain since it usually requires at least one chemical step after the polymerization process.

6.1.1 α -Functional Polymers

A wide range of **TEMPO**, **TIPNO**,^{285–290} or **SG1** alkoxyamines³⁶ bearing a functional group on the alkyl moiety has already been reported. Most of the functionalized alkoxyamines prepared are based on a benzyl chloride moiety and its subsequent chemical transformation. Following this strategy, it has been possible to introduce azido, amino, or alcohol group on the alkyl moiety.^{290,291} Considering a styryl-type derivative as the alkyl moiety, some studies also report the introduction of a functional group at the sp^3 carbon in α position to the carbon linked to the oxygen atom of the nitroxide.^{292–294}

Tordo's group^{49,295} prepared alkoxyamine **12**, commercialized by Arkema under the trademark BlocBuilder MATM.²⁹⁶ The introduction of a carboxylic acid group represented a breakthrough in NMP, both in homogeneous and aqueous dispersed media, thanks to the good solubility of the corresponding sodium salt, for example, in water.⁵⁷ The coupling of this alkoxyamine with alcohols was investigated and it was shown that the combination of high steric hindrance and a high dissociation rate constant prevents

efficient coupling reactions.²⁹⁵ In contrast, the coupling of alkoxyamine **12** with amine-containing compounds was achieved either by preparing the activated ester derivative, **MAMA-NHS 67**,²⁹⁷ or by using a suitable coupling agent, that is, benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (PyBOP).²⁹⁸

A very efficient method for preparing functionalized alkoxyamines was recently proposed and this method relied on the low BDE of **12** to perform quantitative intermolecular radical 1,2-addition onto various olefins (Scheme 9).³⁸ In the case of activated olefins, the challenge consists in avoiding a multiple monomer addition. However, with alkoxyamine **12**, the resulting alkoxyamine after addition bore a less stabilized, bulky secondary radical moiety and to less than the 1-carboxy-1-methyl ethyl radical moiety of the starting alkoxyamine, which prevents further addition.

This reaction was successfully performed at 100 °C in solution with various olefins such as styrene,³⁸ *n*-butyl acrylate,³⁸ 2-hydroxyethyl-acrylate,³⁸ acrylic acid,³⁸ 4-vinyl pyridine,²⁹⁵ styrene sulfonate,²⁹⁵ and *N*-acryloylglucosamine.²⁹⁵ The intermolecular radical 1,2-addition is also useful to prepare di- or triblock copolymers by reacting **12** in the presence of multifunctionalized olefins such as butanediol diacrylate²⁹⁹ or pentaerythritol tri- or tetraacrylate.³⁸

ω -Functional Polymers

The removal or transformation of ω -end-groups of (co)polymers previously made by ATRP and RAFT has often been reported. In contrast, such transformations on ω -end-groups of NMP-made

Scheme 9 Mechanism of the intermolecular radical 1,2-addition.

Figure 13 Various functionalized ω -end-groups accessible for NMP polymers.

macromolecules have not been extensively studied. However, some interesting transformations are now accessible (Figure 13).

The removal of the nitroxide moiety under a radical pathway is probably one of the easiest and most efficient transformations of an NMP-made polymer chain. Typically, the reaction consists in heating the macroalkoxyamine in the presence of an hydrogen donor such as a thiol derivative.^{10,158,261,300} Another famous example of one-step transformation is the reduction of a **TEMPO**-based macroalkoxyamine into the corresponding alcohol in the presence of a mixture of Zn/acetic acid¹⁰ or LiAlH₄.³⁰¹ Interestingly, it was also shown that the direct treatment of polymers containing a **TEMPO** end-group with an oxidant such as *meta*-chloroperbenzoic acid (*m*-CPBA), efficiently affords, at room temperature, the corresponding macromolecular chains bearing a ketone as ω -functional group.³⁰¹

O'Bryan and Braslau³⁰² developed a methodology allowing the preparation of ω -end alcohol, ether, or amide chain-end functionalized polymers

from the corresponding **TIPNO**-polystyryl-based macroalkoxyamines. The strategy consists in exploiting the reactivity of secondary benzylic cations toward various reactants, the latter being obtained after single electron oxidation of the **TIPNO**-polystyryl macroalkoxyamine in the presence of ceric ammonium nitrate.

The use of a non-self-polymerizable monomer (maleimide or maleic anhydride) as a radical trap to prevent multiple radical additions has also been reported as an efficient way to remove and functionalize at the same time an ω -**TIPNO**-polymer moiety.³⁰³

Various other radical traps were investigated. For instance, functionalized or nonfunctionalized tetraethylthiuram disulfide³⁰⁴ compounds were used with **TEMPO**-based polystyrene, whereas benzyl enol ether and ethanesulfonylazide were used with **TIPNO**-based polymers.^{305,306} With polystyryl-**SG1**, one can mention the formation, under radical reaction,³⁰⁷ of the corresponding azide using ethanesulfonylazide, of the corresponding

Figure 14 Synthesis of block copolymers from successive NMP steps.

bromide using ethyl 2-bromoisobutyrate, or of the corresponding polystyryl-macro RAFT agents using benzyl dithiobenzoate and benzyl trithiocarbonate.³⁰⁸

Nitroxide exchange was reported as an efficient tool in introducing valuable functional groups in ω position. For instance, Turro *et al.*,³⁰⁹ Scianio,¹⁵⁴ and Hawker *et al.*^{310,311} performed a direct exchange between **TEMPO**-terminated polystyrene and 4-substituted **TEMPO** derivatives. It should be mentioned that in such cases, the functional group is attached to the polymer chain via a nitroxide linkage that is thermolabile and therefore restricted to specific applications. Since the direct treatment of polystyryl-**SG1** with either Zn/AcOH, or LiAlH₄, or *m*-CPBA was not conclusive, Guilleaume *et al.*³⁰⁷ exploited the nitroxide exchange strategy to efficiently replace the **SG1** moiety by a **TEMPO** moiety. This approach combined with the methods already developed by Rizzardo¹⁰ and Pionteck³⁰¹ allowed hydroxyl- and keto-functionalized polymers to be obtained from polystyryl-**SG1** macroalkoxyamine.

6.2 NMP-Made Diblock and Triblock Copolymers

In order to fulfill specific criteria, novel polymeric materials exhibiting increasingly sophisticated properties and performances are desired. It is well established that a desired combination of physical and chemical properties, not achievable via homopolymers, can be obtained by designing tailor-made block, graft-, and other types of copolymers. In this context, intense efforts have been devoted to the development of novel strategies allowing the convenient synthesis of block copolymers. Indeed these materials whose access has been incredibly facilitated, thanks to the progress made in CRP, are obtained by covalent bonding of two or more chemically different polymeric chains that, in most cases, are thermodynamically incompatible, giving rise to a rich variety of microstructures in bulk and

in solution and therefore to a fine tuning of the associated materials properties.

Regarding the NMP technique, the most widely applied synthetic pathway for obtaining a block copolymer is the sequential polymerization of different monomers (Figure 14). After polymerization of the first monomer, the resulting macroinitiator could be either used *in situ* or purified/separated prior to further chain extension, the latter option being usually the most preferred one to achieve purity for the second block. Following this strategy, a wide range of block copolymers has already been prepared.

A number of specific techniques have also been developed for the preparation of block copolymers such as the coupling reaction or the use of a heterofunctional alkoxyamine (Figure 15).

Typically, heterofunctional initiators^{312–314} are designed for the synthesis of block copolymers composed of monomer units that require different polymerization mechanisms. The interest of this approach has been highlighted for the combination of NMP, with anionic polymerization, ROP, ring opening metathesis polymerization (ROMP), or other CRP techniques.

7 APPLICATIONS

The development of controlled radical polymerization techniques has enabled extraordinary opportunities in the synthesis of new materials such as block copolymers³¹⁵ mainly designed for a broad range of applications³¹⁶ specialty such as detergents, cosmetics, health, paints, coatings, adhesives, electronics, transport, or energy. As a consequence, strong efforts are devoted to building up precise correlations between composition/architecture of the micro and macroscopic properties and the development of analytical methodologies for the precise characterization of increasingly sophisticated polymer architectures and compositions.

Among the available controlled radical polymerization methods, NMP is of particular interest because of its tolerance of many functional groups,

Figure 15 Possible synthesis of block copolymer from a heterofunctional alkoxyamine (with • = functional group such as OH, NH, SH, COOH, ...).

the absence of metal catalysts, as well as coordinating ligands, or sulfur-containing moieties. For instance and as highlighted by Fréchet *et al.*³¹⁷ such consideration is important when synthesizing electroactive from ligand-functionalized monomers, and the presence of catalyst residues might impair device performance. Interestingly, NMP is also well suited for the preparation of peptide–polymer conjugates.^{298, 318–321}

8 PERSPECTIVES

We can state that in only 25 years, the development of the CRP techniques including NMP has changed completely the rules in the field of polymer materials, opening up possibilities in both advanced polymer synthesis and polymer physics that until recently were either difficult or impossible to achieve. Thanks to both a deep investigation on the physico-chemical behaviors of various nitroxide/alkoxyamine^{6,26,45} and the synthesis of more efficient nitroxide/alkoxyamines,^{41,49,69,205,206,322–326} NMP has benefited from significant improvements since Rizzardo's pioneering work.^{10,11} However, NMP still suffers from some drawbacks and further improvements are highly desired. In order to reach this goal, fundamental mechanistic and kinetic studies of

NMP are still necessary. For instance, relationships between the nitroxide structure and the recombination rate constant of the macroradical have to be established. The presence and the effects of undesired side-reactions between the nitroxide and the propagating radical chain such as the hydrogen abstraction reaction need to be carefully investigated as they play a dramatic role on the fate of NMP.⁴⁵ Moreover, although NMP has been often investigated using semiempirical methods, a quantitative approach relying on more recent calculation methods is needed to get deeper insight on the effects of the alkoxyamine structure on each reaction involved for each stage.^{212,214}

On the polymer preparation side, an universal nitroxide/alkoxyamine allowing the preparation of block copolymers composed of styrene, acrylates, and methacrylates monomers (or any 1,1- and monosubstituted monomers) by NMP is still missing. In addition, homo NMP of vinyl acetate³²⁷ and *N*-vinyl pyrrolidone are not yet achieved and also represent exciting challenges that deserves to be investigated with respect to the importance of the applications of the polymeric materials based on poly-vinylacetate or poly-*N*-vinylpyrrolidone.³²⁸

Besides these works based on the NMP process initiated under thermal conditions, we can expect, in the near future, an intensification of studies focused on nitroxide-mediated photopolymerization

Figure 16 Principle of nitroxide-mediated photopolymerization (with • = chromophore group).

NMP2 (Figure 16). Indeed, Gigmes *et al.*^{329–331} showed very recently that by a careful selection and synthesis of photosensitive alkoxyamines, partial control of photopolymerization of *n*-butyl acrylate was possible. It has to be mentioned that photopolymerization represents a rapidly emerging field in material science, mainly due to the numerous advantages associated to UV irradiation (very fast polymerization <1 s, no volatile organic compounds released, etc.).³³² For coatings, inks, photoresists, or dual-cure systems, the photopolymerization is now recognized as particularly interesting and efficient.³³³ However, the main drawback of the photochemical processes is the lack of control of the polymer properties and the difficulty to prepare block copolymers. Therefore in this context, the development of NMP2 is very appealing and could represent a competitive alternative to photoiniferter technology, introduced by Otsu and Yoshida.^{334,335}

Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications

Tomislav Pintauer¹ and Krzysztof Matyjaszewski²

¹Department of Chemistry and Biochemistry, Duquesne University, Pittsburgh, PA, USA and

²Department of Chemistry, Carnegie Mellon University, Pittsburgh, PA, USA

1 INTRODUCTION AND BACKGROUND

1.1 The Origins of Atom Transfer Radical Addition—"Peroxide Effect"

The origins of atom transfer radical addition (ATRA) can be traced back to 1937 when Kharasch and coworkers discovered "the peroxide effect" which accounted for anti-Markovnikov addition of HBr to unsymmetrical alkenes in the presence of peroxide initiators.¹ The generally accepted mechanism for this reaction involves free-radical intermediates, as outlined in Scheme 1. Soon after the discovery of the "peroxide effect," it was recognized that a variety of substrates such as hydrocarbons, polyhalogenated alkanes, alcohols, ethers, amines, aldehydes, ketones, aliphatic acids, and esters, as well as compounds of sulfur, phosphorous, silicon, tin, and germanium, can be used in the radical addition to alkenes. In particular, Kharasch investigated the addition of polyhalogenated alkanes (CBr₄, CCl₄, CBr₃Cl, and CCl₃Br) to alkenes in the presence of free-radical initiators or light (Scheme 2), in a reaction that is today widely referred to as the *Kharasch addition* or *atom transfer radical addition* (ATRA).^{2–4} Very high yields of the monoadduct were obtained in the case of

simple α -olefins (1-hexene, 1-octene, and 1-decene), but they were significantly low for more reactive monomers such as styrene, methyl acrylate, and methyl methacrylate (MMA). The principal reason for the decreased yield of the monoadduct was radical–radical termination and repeating radical addition to alkene to generate oligomers and polymers. Although radical–radical termination reactions by coupling and disproportionation could be suppressed by decreasing the radical concentration ($R_t \propto [\text{radicals}]^2$), telomerization reactions could not be avoided because of the low chain transfer constant (k_{tr}/k_p , Scheme 2). The research was thus shifted in the direction of finding a means to selectively control the product distribution.

1.2 Fundamentals of Transition-Metal-Catalyzed Atom Transfer Radical Addition (ATRA)

The principal drawback of nontransition-metal-catalyzed (TMC) ATRA was the inability to control the chain transfer constant (k_{tr}/k_p , Scheme 2). This resulted in significantly lower yields of the monoadduct for monomers that are highly active in free-radical polymerization, such as styrene, methyl

Table 1 Chain transfer constants for CCl₄ in free-radical polymerization at 60 °C.^{5,6}

Alkene	$k_{tr}(M^{-1} s^{-1})$	$k_p(M^{-1} s^{-1})$	k_{tr}/k_p
Ethylene	259	79	3.28
1-Hexene	320	87	3.68
Vinyl acetate	2400	8 300	0.289
Acrylonitrile	0.17	3 200	5.31×10^{-5}
Methyl acrylate	0.26	28 000	9.30×10^{-6}
Methyl methacrylate	0.12	821	1.46×10^{-4}
Styrene	1.8	331	5.44×10^{-3}

acrylate, MMA, and acrylonitrile (Table 1). Clearly, a search for a better halogen atom transfer agents was needed.

In 1956, Minisci *et al.* attempted thermal polymerization of acrylonitrile in CCl₄ and CHCl₃ in a steel autoclave and observed considerable amounts of monoadduct (CCl₃–CH₂–CHClCN with CCl₄ and CHCl₂–CH₂–CHClCN with CHCl₃).⁷ These results were unexpected because the chain transfer constants (k_{tr}/k_p) of CCl₄ (Table 1) and CHCl₃ are not high enough to prevent polymerization of acrylonitrile. In 1961, on the grounds of analogous redox haloalkylations of acrylonitrile, the same authors proposed a mechanism in which iron chlorides (arising from corrosion of the autoclave) played a major role in this process by increasing the chain transfer

constant.^{8–13} This reaction marked the beginning of TMC ATRA. Since the seminal report by Minisci *et al.*, a number of species were found to be particularly active in the ATRA process, which included the complexes of Cu, Fe, Ru, and Ni,^{14–19} as well as metal oxides^{20,21} and zero-valent metals such as Cu(0)^{22,23} and Fe(0).^{24–26} Great progress has been made in not just controlling the product selectivity, but also in utilizing a variety of halogenated compounds (alkyl and aryl halides,^{12,27,28} *N*-chloroamines,¹² alkylsulfonyl halides,^{29–34} and polyhalogenated compounds^{29,34–36}). Furthermore, it was also demonstrated that a variety of alkenes (styrene, alkyl acrylates, and acrylonitrile) could be used as the source of reactive unsaturation. Therefore, TMC ATRA became a broadly applicable synthetic tool.^{15–17,37,38}

Based on chemo-, regio-, and stereoselectivity, it is generally accepted that the mechanism of TMC ATRA involves free-radical intermediates.^{12,29,39,40} The proposed mechanism in the case of copper complexes is shown in Scheme 3. Homolytic cleavage of an alkyl halide bond by a copper(I) complex generates a corresponding copper(II) complex and an organic radical ($k_{a,1}$). The radical may terminate (k_t) or add to an alkene (k_{add}) in an inter- or intramolecular fashion or it can abstract the halogen atom from the copper(II) complex and return to the original

Scheme 3 Proposed mechanism for copper-catalyzed ATRA.

dormant alkyl halide species ($k_{d,1}$). If the abstraction of the halogen atom occurs after the first addition to an alkene, the desired monoadduct will be formed ($k_{d,2}$). This step regenerates the corresponding copper(I) complex and therefore completes the catalytic cycle. There are several guidelines that should be followed in order to increase chemoselectivity of the monoadduct. Firstly, the radical concentration must be low in order to suppress radical termination reactions (rate constants of activation [$k_{a,1}$ and $k_{a,2}$] $\ll$ rate constants of deactivation [$k_{d,1}$ and $k_{d,2}$]). Secondly, further activation of the monoadduct should be avoided ($k_{a,1} \gg k_{a,2}$, ideally $k_{a,2} \approx 0$). Lastly, formation of oligomers should be suppressed, indicating that the rate of deactivation ($k_{d,2}[\text{Cu(II)L}_m\text{X}]$) should be much larger than the rate of propagation ($k_p[\text{alkene}]$). Alkyl halides for copper-catalyzed ATRA are typically chosen such that, if addition occurs, then the newly formed radical is much less stabilized than the initial radical and will essentially irreversibly react with a copper(II) complex to form an inactive monoadduct.

TMC ATRA reactions can also be conducted intramolecularly when alkyl halide and alkene functionalities are part of the same molecule. Intramolecular TMC ATRA or atom transfer radical cyclization (ATRC) is a very attractive synthetic tool because it enables the synthesis of functionalized ring systems that can be used as starting materials for the preparation of complex organic molecules.^{17,38,41–43} Furthermore, the halide functionality in the resulting product can be very beneficial because it can be easily reduced, eliminated, displaced, converted to a Grignard reagent, or, if desired, made to serve as a further radical precursor.³⁹

1.3 Fundamentals of Transition-Metal-Catalyzed Atom Transfer Radical Polymerization (ATRP)

In 1995, a new class of controlled/“living” radical polymerization method was reported by the groups of Wang and Matyjaszewski⁴⁴ and Sawamoto.⁴⁵ This new process, named *atom transfer radical polymerization* (ATRP),⁴⁴ has had a tremendous impact on the synthesis of macromolecules with well-defined compositions, architectures, and functionalities.^{46–63}

Mechanistically, copper-catalyzed ATRP is similar to ATRA with the exception that the reaction conditions are modified in such a way that more than one addition step occurs. As indicated in Scheme 4, a homolytic cleavage of an alkyl halide bond (RX) by a copper(I)/2,2'-bipyridine complex generates an alkyl radical and a corresponding copper(II)/2,2'-bipyridine complex. The newly formed radicals can initiate polymerization by addition across a double bond of a vinyl monomer, propagate, or terminate by either coupling or disproportionation, or be reversibly deactivated by the copper(II) bipyridine complex. In ATRP, formation of radicals is reversible and the stationary radical concentration is low because the equilibrium between the activation (k_a) and deactivation (k_d) processes, $K_{\text{ATRP}} = k_a/k_d$, is strongly shifted to the left-hand side ($k_a \ll k_d$). This in turn minimizes radical termination reactions and enables synthesis of polymers with predetermined molecular weights, narrow molecular weight distributions, and high functionalities.⁴⁷

Copper-catalyzed ATRP is well suited for the preparation of copolymers with controlled

Scheme 4 Proposed mechanism for copper(I)/2,2'-bipyridine-catalyzed ATRP.

Figure 1 Schematic representation of polymers with controlled topology, composition, and functionality synthesized using copper-catalyzed ATRP. [Reproduced from Ref. 64. With permission of Springer Science + Business Media.]

topologies, including star- and comb-like polymers, as well as branched, hyperbranched, dendritic, network, and cyclic type structures.^{46,47,53,55,56} The basic strategies for producing polymeric materials by ATRP are illustrated in Figure 1 and more specific examples will be discussed later. Similarly, particularly with recent advances in catalyst regeneration techniques, copper-catalyzed ATRA and intramolecular version ATRC are becoming synthetically useful for the construction of small organic molecules (see below).

2 BASIC COMPONENTS OF ATRP

Copper-catalyzed ATRP is a multicomponent system, and it is composed of the monomer, an initiator with a transferable (pseudo)halogen, and a copper complex (composed of a copper(I) and copper(II) (pseudo)halide and usually nitrogen-based complexing ligand). Sometimes an additive is used. For a successful ATRP, other factors, such as solvent and temperature, must also be taken into consideration.

2.1 Monomers

Copper-catalyzed ATRP is applicable to a wide range of monomers that contain an α -stabilizing

substituent adjacent to the transferable atom or group (Scheme 5). Such substituents provide efficient reactivation of the dormant chains. The initial range of monomers that could be polymerized by ATRP included styrenes,⁴⁴ (meth)acrylates,⁶⁵ meth(acrylamides),^{66,67} and acrylonitrile.^{68–72} Subsequently, ATRP was expanded to include several functional monomers, including 4-vinylpyridine,^{73–76} monomers containing OH-group, such as 2-hydroxyethyl acrylate (HEA),⁷⁷ 2-hydroxyethyl methacrylate (HEMA),^{78–80} and glycidyl acrylate,^{70,80–82} and precursors of ionic monomers⁸³ including dimethylamino methacrylate (DMAEMA),^{84–86} 2-(trimethylammonium)ethyl methacrylate trifluoromethanesulfonate, and 2-(dimethylammonium)ethyl methacrylate bromide.⁸⁷ Glycidyl acrylate⁸³ has also been copolymerized by ATRP, yielding well-defined polymers containing the reactive glycidyl group which can be used as a precursor for other functional groups.⁸² Furthermore, both neutral and ionic water-soluble monomers can be polymerized in a controlled fashion by ATRP in protic (aqueous) media.⁶² Some representative examples of monomers, including those with polar groups, are shown in Scheme 5. Additionally, simple alkenes have been copolymerized by ATRP with polar monomers.^{88–91} Recent improvements in catalysis and expansion of suitable transferable atoms or groups have also

Scheme 5 Examples of functionalized monomers that can be polymerized by ATRP.

allowed successful ATRP of *N*-vinylpyrrolidone,⁹² vinyl acetate,⁹³ and vinyl chloride.⁹⁴

The major differences between the polymers prepared by ATRP and conventional free-radical polymerization are the additional degrees of control over the architecture, molecular weight, molecular weight distribution, and telechelic functionality. In addition to low molecular weight monomers, a broad range of macromonomers have been copolymerized with low molecular weight monomers to form graft copolymers^{95–97} and even homopolymerized to form bottle-brush polymers.^{98–100}

2.2 Initiators

The polymer growth in ATRP starts by homolytic cleavage of a carbon–halogen bond in an initiator, commonly denoted as R–X (Scheme 4). The initiator in ATRP can be a small molecule, a macromolecule, or a functionalized surface of any topology, with one or more radically transferable atoms or groups.¹⁰¹ The best results have been obtained when X has been either a chlorine or bromine, but iodine has also been successful with acrylates, vinyl acetate, and vinyl chloride.^{93, 102–105}

For a successful ATRP, appropriate combination of the initiator, catalyst, and reaction conditions must be selected. The primary reason is to provide control over the efficiency of the initiation reaction.¹⁰⁶ Shown in Figure 2 is the variation between the activation rate constant (k_a , Scheme 4) and structure of the initiator and transferable atom. Generally, the activation rate constants are highest for

tertiary alkyl halides, followed by secondary ones. Primary alkyl halides typically have very low activation rate constants and are generally poor initiators for ATRP. The activity of alkyl bromides is several times larger than that of the analogous alkyl chlorides in reactions mediated by the same catalyst complex. Additionally, polymers prepared by other polymerization processes can be functionalized at the termini or along the backbone and incorporated into an ATRP as macroinitiators.^{107–110} Such methodology leads to the preparation of well-defined block and graft copolymers comprising a broader range of monomers. Furthermore, the initiator(s) can be attached to any type of polymer, or a solid surface¹¹¹ (particle,¹¹² fiber,¹¹³ porous material,¹¹⁴ etc.), leading to chain growth in several directions. A functional initiator may carry a second noninitiating functionality, in addition to a radically transferable atom or group, to yield hetero-telechelic materials.¹¹⁵ Since ATRP is a radical process, many functional groups can be tolerated in the initiator molecule, including hydroxy, epoxy, amino, amido, cyano, and azido groups. Additionally, several other ones can be incorporated in a protected form.

2.3 Complexing Ligands in Copper-Catalyzed ATRP

The primary role of the complexing ligand in ATRP is to solubilize the copper salts and tune the catalytic activity to optimally conduct a well-controlled polymerization. Neutral nitrogen-based complexing ligands are typically used in copper-catalyzed

Figure 2 Variation of activation rate constants (k_a in $\text{M}^{-1} \text{s}^{-1}$) based on structure of initiator and transferable atom. [Reproduced with permission from Ref. 116. Copyright 2008 American Chemical Society.]

ATRP. Some representative examples are shown in Scheme 6. Depending on the type of amine ligand, the complexes are either neutral (triamines) or ionic (bpy and tetramines).¹¹⁷ The counterions in the case of the ionic complexes are either a bromide anion (Me_4CYCLAM and HMTETA) or the linear Cu(I)Br_2^- (dNbpy), but this also depends strongly on the solvent. No direct correlation was found between the Cu(II)-Br bond length and the deactivation rate constant (k_d , Scheme 6) in ATRP, which suggested that other parameters, such as the entropy for structural reorganization between the copper(I) and copper(II) complexes, might play an important role in determining the overall activity of the catalyst in ATRP.¹¹⁷

As discussed in the kinetic section (see below), the ratio of activity for the copper(I)/ligand and initiators each spans over seven orders of magnitude. The general order of activity of the copper complex formed with specific type of ligand is Cyclam > N4-branched > N4-linear > N3 > N2. Anionic

ligands form stable and active neutral copper complexes, but their deactivation rate constants are low.^{118,119} Because of the high stability of copper(I) and copper(II) complexes with TPMA, this catalyst is particularly suitable for activators regenerated by electron transfer (ARGET) and initiators for continuous activator regeneration (ICAR) ATRP (see below).¹²⁰ More detailed information about structural and mechanistic aspects of copper-catalyzed ATRA and ATRP can be found in several recently published review articles.^{40,59,60,64,121}

2.4 ATRP with Other Transition Metals

ATRP has been successfully mediated by a variety of metals, including those from groups IV (Ti¹²²), VI (Mo^{123–125}), VII (Re¹²⁶), VIII (Fe^{127–130}, Ru^{45,131} and Os^{132,133}), IX (Rh¹³⁴ and Co¹³⁵), X (Ni^{136,137} and Pd¹³⁸), and XI (Cu^{44,57,139}). Copper complexes have been the most thoroughly

Scheme 6 Examples of neutral nitrogen-based complexing ligands suitable for preparing copper-based catalysts for ATRP.

investigated in ATRP and are perhaps the most efficient catalysts based on a broad range of monomers and applicability to diverse reaction media.^{59,64} Some complexes based on Co, Mo, and Os form reversibly organometallic species and usually do not operate via the halogen atom transfer mechanism.¹⁴⁰ However, several complexes based on Fe (Scheme 7) and Ru (Scheme 8) will also be briefly discussed in this section. Iron attracts large attention because it is the least toxic and expensive transition metal. Ruthenium complexes, together with copper, were first used in ATRP and also ATRA reactions.

Iron complexes were first used with monodentate ligands such as phosphines, phosphites,

and amines (**Fe-1** to **Fe-3**). Iron complexes with bidentate ligands such as bipyridines and α -diimines were also successfully applied (**Fe-4** to **Fe-10**). The activity of iron α -diimine complexes depends strongly on the nature of R groups. Generally, with electron-donating substituents well-controlled ATRP was observed. However, with electron-withdrawing groups, oligomerization and transfer were detected.^{141–143} Computational, reactivity, and mechanistic studies indicated that this switch in polymerization mechanism correlates with a change in the metal spin state in the corresponding Fe(III) complexes, with electron-withdrawing groups stabilizing the intermediate-spin state ($S = 3/2$) complexes and

Scheme 7 Examples of iron complexes used in ATRP.

Scheme 8 Examples of ruthenium complexes used in ATRP.

electron-donating groups supporting the high-spin ($S = 5/2$) species.^{144,145} The observed transfer is caused by β -H elimination from a postulated Fe(III)–R intermediate.

Complexes most active in ATRP are based on half-metallocenes (**Fe-11**). They were successful in

polymerization of various monomers. With ethyl 2-iodoisobutyrate as the initiator, they were active even in polymerization of vinyl acetate, presumably by degenerative transfer mechanism.¹⁴⁶

Fe(II)X₂ together with ammonium or phosphonium chloride, bromide, or iodide salts induced

the controlled polymerization of both styrene and methacrylates.¹³⁰ Structures **Fe-12** to **Fe-15** represent iron complexes that may be involved in the polymerization process. This has been the first example of negatively charged ATRP activators. The reverse ATRP initiated by AIBN/FeBr₃/onium salts led to a controlled polymerization of both methyl methacrylate and methyl acrylate. Recently, an improved version of the system using phosphazanium halides with FeBr₂ for the polymerization was reported.¹⁴⁷ The best catalytic performance was found when an equimolar mixture of ligand and metal salt was used, which is indicative of the formation of a 1 : 1 anionic complex.

ATRP of methyl methacrylate catalyzed by FeBr₂ with several ionic liquids bearing various counterions in absence of added organic ligand was also successful.¹⁴⁸ In mixtures with toluene, at 60–70 °C and with EBiB (ethyl 2-bromoisobutyrate) as the initiator, molecular weights increased linearly upon conversion. In the presence of small amounts of FeBr₃, an enhanced control of the polymerization was observed. The ionic liquids containing the transition-metal salts could be efficiently separated from the polymerization media and regenerated. This has been the first example of an ionic liquid acting as a true catalytic species.

Recently, ATRP of methyl methacrylate in polar solvents was successfully catalyzed by FeBr₂ in the absence of any additional ligand.¹⁴⁹ The polymerizations were well controlled in *N*-methylpyrrolidone (NMP), dimethylformamide (DMF), and MeCN. The molecular weights agreed well with the theoretical values and molecular weight distributions were relatively narrow ($M_w/M_n < 1.3$). These solvents might play the role of efficient ligands for FeBr₂. However, there was no control in dimethylsulfoxide (DMSO), which may coordinate to Fe too strongly. The concentration of NMP in methyl methacrylate can be as low as 10% (v/v), leading to a relatively fast polymerization at 60 °C. The conversion reached 55% in 100 min, providing poly(methyl methacrylate) with a molecular weight of $M_n = 5200$ g/mol and $M_w/M_n = 1.21$. Addition of a small amount of FeBr₃ improved the level of control in these systems.

Apart from copper and iron, ruthenium complexes have also been extensively used in ATRP. The first application of Ru-based catalysts in ATRP was with phosphine ligands, as an extension of

similar ATRA systems. Typically, they are soluble in nonpolar media (**Ru-1**) but complexes **Ru-2** have been also used in aqueous media. There are several Ru catalysts with carbon-based ligands, such as half-metallocene (**Ru-3**), which are also water soluble (**Ru-4**). Many Ru-based catalysts require some additives/cocatalysts, such as Al compounds or amines that increase their activity. However, air-stable complexes [RuCl₂(p-cymene)(PR₃)] (**Ru-5** to **Ru-13**) promote the controlled radical polymerization (CRP) of several vinyl monomers without the presence of a cocatalyst.¹³¹ The highest catalytic activity with a narrow molecular weight distribution was obtained with phosphines that were strongly basic and with a well-defined steric bulk ($160^\circ < \theta < 170^\circ$, θ = cone angle of the phosphine). In fact, typical ROMP (ring-opening metathesis polymerization) catalysts are also active in ATRP, and a catalyst (**Ru-14**) successfully mediated three different reactions (ROMP, ATRP, and hydrogenation of olefins) at the same time.^{150,151} This allowed preparation of various block copolymers without need of end group transformation.

2.5 Additives

Additives are sometimes added to ATRP reactions in order to modify the reaction kinetics and control over molecular weight and molecular weight distribution. In addition to various reducing agents, including sugars, phenols, tin(II) compounds, copper(0), or free-radical initiators initially added to activate and reactivate copper(II) complex in activators generated by electron-transfer (AGET), ARGET, and ICAR initiating systems (see below), one can also include the addition of specific agents to modify the equilibrium constant for atom transfer ($K_{\text{ATRP}} = k_a/k_d$), including solvents such as tertiary amines,¹⁵² pyridine,¹⁵³ malonitrile,¹⁵⁴ phenol,¹⁵⁵ antioxidants,¹⁵⁶ water,¹⁵⁷ or inorganic halides.⁸⁷

3 INITIATING ATRP

A successful ATRP process should meet several requirements. Firstly, the initiator should be consumed in the early stages of polymerization and

generate propagating chains leading to polymers with degrees of polymerization (DPs) predetermined by the ratio of concentrations of the converted monomer (M) to the introduced initiator (I), $DP = \Delta[M]/[I]_0$. Secondly, the number of monomer molecules added during one activation step should be small, resulting in polymers with low polydispersity index ($PDI = M_w/M_n$). Finally, the contribution of chain-breaking reactions, such as transfer and termination, should be negligible, enabling the synthesis of polymers with high degrees of end functionality.

According to Scheme 6, neglecting the termination reactions due to the persistent radical effect and using a fast equilibrium approximation, the rate law for ATRP can be derived as follows:

$$-\frac{d[M]}{dt} = k_p[M][P^*] = \frac{k_p K_{ATRP}[M][PX][Cu(I)]}{[X-Cu(II)]} \quad (1)$$

where $K_{ATRP} = k_a/k_d$. According to (1), the polymerization rate in ATRP depends on the equilibrium constant for ATRP (K_{ATRP}), concentrations of the dormant species [PX] and monomer [M], propagation rate constant of monomer (k_p), and the ratio of the concentrations of activator [Cu(I)] and deactivator [X-Cu(II)]. On the other hand, the molecular weight distribution or PDI in ATRP depends on the propagation rate constant (k_p), deactivation rate constant (k_d), monomer conversion (p), and the concentrations of dormant species, monomer, and deactivator [X-Cu(II)] according to (2):

$$\frac{M_w}{M_n} = 1 + \left(\frac{[PX]k_p}{k_d[X-Cu(II)]} \right) \left(\frac{2}{p} - 1 \right) \quad (2)$$

Shown in Figure 3a is a typical linear variation of conversion with time in semilogarithmic coordinates observed in metal-mediated ATRP. The plot indicates that there is a constant concentration of active species in the polymerization and first-order kinetics with respect to monomer. Furthermore, a plot of polymer molecular weight versus conversion is linear, indicating constant number of polymer chains (Figure 3b). Also, the molecular weight distribution (M_w/M_n) or PDI typically decreases with conversion, and in a well-controlled process it approaches the value that is usually less than 1.10 (Figure 3c).⁵⁷

There are presently several different ways to set up ATRP equilibrium shown above in Scheme 4, and they are discussed in detail below.

Figure 3 Typical kinetic features of copper-catalyzed ATRP. [Ref. 120 - Reproduced by permission of The Royal Society of Chemistry, 2008.]

3.1 Reverse ATRP

In 1995, it was established that ATRP equilibrium can be approached from both sides. A standard or “normal” ATRP process starts with an initiator and a transition-metal complex in the lower oxidation state.^{44,65} This combination can sometimes present a problem, specially if highly active complexes are used that can be easily oxidized if traces of oxygen are present in the reaction mixture. However, the spontaneous oxidation can also increase the efficiency of initiation from RX because radical termination reactions required to form the persistent radical or transition-metal complex in the higher oxidation state can be avoided or reduced.¹⁵⁸

In the initial example of reverse ATRP process,⁶⁵ the reduction of the deactivator (copper(II) complex) by the radicals generated from thermal decomposition of conventional free-radical initiators, such as 2,2'-azobis(isobutyronitrile) (AIBN)¹⁵⁹ or benzoyl peroxide (BPO),¹⁵⁹ was used to regenerate both the activator (copper(I) complex) and ATRP initiator. The proposed mechanism is shown in Scheme 9. Free radicals that are initially present in the system can also initiate polymerization; however, growing polymer chains are rapidly deactivated by the copper(II) complex to form dormant chains and

Scheme 9 Proposed mechanism for reverse ATRP.

copper(I). Thereafter, the reaction proceeds as normal ATRP. In another variation of this process, copper(0) metal can also be used as a reducing agent.^{160–162} One of the main advantages of reverse ATRP is the ability to start the reaction with oxidatively stable copper(II) complex, which allows a simple experimental setup and eliminates problems associated with oxidation of highly active copper(I) complexes.

3.2 Simultaneous Reverse and Normal Initiation

An improved reverse ATRP was developed to take advantage of the ability to use more active or readily oxidized complexes.^{163,164} This procedure was named simultaneous reverse and normal initiation (SR&NI) because the activator and a small fraction of initiating chains were formed in a “reverse” ATRP reaction, while the majority of the growing polymer chains were initiated from the added normal ATRP initiator molecule.

3.3 Activators Generated by Electron Transfer ATRP

The limitation of normal and simultaneous reverse initiation in copper-mediated ATRP is evident in

the inability of these techniques to produce clean block copolymers. In AGET ATRP, stoichiometric amounts of the reducing agents are added to the reaction mixture containing alkyl halide, monomer, and the air-stable deactivator (X-Cu(II)) to regenerate the activator (Cu(I)). After the regeneration of the activator (Cu(I)), the polymerization kinetics resembles that of conventional ATRP. AGET ATRP utilizes reducing agents that are unable to initiate new polymer chains, such as zero-valent copper, tin(II) 2-ethylhexanoate, ascorbic acid, or triethylamine.^{62,160,161,165,166} This technique has been shown to be particularly useful in aqueous and mini emulsion systems.^{165,167–169}

3.4 Activators Regenerated by Electron Transfer ATRP

An ATRP catalyst that is sufficiently stable and active can be used at very low concentrations. However, it is very important to realize that the lower oxidation state of the catalyst (the Cu(I) complex in the case of copper-mediated ATRP) is constantly being converted to a higher oxidation state complex (X-Cu(II)) as a result of unavoidable radical termination reactions. Therefore, the deactivator (X-Cu(II)) will accumulate in the system as the reaction proceeds. The amount of lost Cu(I) complex due to termination is equal to the amount of terminated chains, as shown by (3).

$$\begin{aligned}
 -\Delta[\text{Cu(I)L}_m] &= \Delta[\text{X-Cu(II)L}_m] \\
 &= \Delta[\text{P}_{\text{dead}}] = k_t[\text{P}^{\bullet}]^2 t \quad (3)
 \end{aligned}$$

Furthermore, the accumulation of the deactivator (X-Cu(II)) results in the slowing down of the polymerization rate, which in turn limits high monomer conversions. ARGET ATRP is similar to AGET ATRP, with the exception that it utilizes much smaller concentrations of the activator (Cu(I)) and consequently large excess of the reducing agent.^{170–172} As a result, copper(II), which accumulates as a persistent radical during ATRP, is continuously reduced to the corresponding copper(I) complex. Copper(I) complex is needed to homolytically cleave the alkyl halide bond (R-X). As indicated in (1), the rate of monomer consumption in ATRP depends on the absolute ratio of the concentrations of the activator (Cu(I)) and deactivator

Scheme 10 Proposed mechanism for regeneration of copper(I) complex in ARGET and ICAR ATRP.

(X–Cu(II)). Therefore, the absolute amount of copper catalyst in ATRP can be decreased under normal ATRP conditions without affecting the rate of polymerization. In ARGET ATRP, the presence of a large excess of the reducing agent ($Sn(EH)_2$, glucose, or ascorbic acid) enables the polymerization to be conducted using very small amounts of copper catalysts (Scheme 10). Furthermore, the excess of reducing agent can also be used to consume oxygen and other inhibitors from the reaction mixture and eliminate deoxygenation step. Apart from homo- and copolymerizations, this process can also be applied to grafting from various surfaces.¹⁷³

3.5 Initiators for Continuous Activator Regeneration

As discussed earlier, radical termination reactions lead to the irreversible accumulation of persistent radical or deactivator (X–Cu(II) complex) under typical ATRP conditions. In other words, if the initial catalyst concentration is too low, all of the activator will eventually be consumed as a persistent radical and polymerization will only reach limited conversions. A new technique known as *initiators for continuous activator regeneration* in ATRP can be used to both scavenge oxidants and also decrease the amount of catalyst.¹⁷⁴ In

ICAR ATRP, free radicals are slowly and continuously generated by conventional radical initiators (e.g., AIBN) throughout the polymerization to constantly reduce the copper(II) complex that accumulates as a persistent radical (Scheme 10). With this technique, controlled synthesis of polystyrene and poly(meth)acrylates ($M_w/M_n < 1.2$) can be conducted with catalyst concentrations between 5 and 50 ppm levels, at which removal or recycling of the catalyst would be unnecessary for many applications. The reaction is typically driven to completion with low concentrations of added standard free-radical initiators. Computer simulations confirmed that the rate of polymerization in ICAR ATRP is governed by the rate of free-radical initiator decomposition, while the degree of control, the rate of deactivation, and molecular weight distribution are controlled by K_{ATRP} , as in ATRP.¹⁷⁴ This method of catalyst regeneration has also been utilized with great success in mechanistically similar ATRA and ATRC.^{39,40,120,175–181}

4 ATRP THERMODYNAMICS AND KINETICS

Mechanistically, ATRP is a complex process based on several elementary reactions. Similarly to conventional free-radical polymerization, elementary reactions in ATRP consist of initiation,

propagation, and termination, which are systematically evaluated using pulse laser polymerization techniques and electron paramagnetic resonance (EPR) measurements.^{6,182} Perhaps, the most important reaction parameters in ATRP are activation (k_a) and deactivation (k_d) rate constants, and consequently equilibrium constant for atom transfer ($K_{\text{ATRP}} = k_a/k_d$). They strongly depend on the structure of alkyl halide, monomer, solvent, temperature, and, more importantly, the copper complex. Systematic evaluation of K_{ATRP} , k_a , and k_d is crucial in further understanding of the ATRP mechanism and can provide information about the nature and reactivity of active intermediates, as well as factors needed to design more active catalysts that can be used in smaller concentrations and also polymerize currently inactive monomers. The following paragraphs will outline the strategies in mechanistic understanding of ATRA and ATRP reactions.

4.1 Equilibrium Constants in ATRP

The equilibrium constant for ATRP ($K_{\text{ATRP}} = k_a/k_d$) provides critical information about the position of dynamic equilibrium between dormant and active species during polymerization (Scheme 4). The value of K_{ATRP} can be easily accessed from the polymerization kinetics using the $\ln([M]_0/[M]_t)$ versus t plots with a slope $K_{\text{ATRP}}k_p[\text{RX}][\text{Cu(I)}]/[\text{Cu(II)}]$. If sufficient initial excess of Cu(II) species is used, then its concentration, as well as that of the other reagents, does not change, and K_{ATRP} value can be determined by knowing k_p . Alternatively, K_{ATRP} can be obtained from model studies using modified analytical solution of the persistent radical effect,¹⁸³ originally developed by Fischer^{184–186} and Goto and Fukuda.¹⁸⁷

Values of K_{ATRP} strongly depend on the complexing ligand, halogen, alkyl group, as well as the solvent and the temperature.

4.2 Activation Rate Constants in ATRP

It is not possible to determine from K_{ATRP} alone whether the polymerization will be controlled; fast activation and, more importantly, fast deactivation are required to achieve good control

over polymer molecular weights and molecular weight distributions. Therefore, precise measurements of the activation (k_a) and deactivation (k_d) rate constants should be used for correlation with catalyst, alkyl halide, and monomer structures.

Activation rate constants (k_a) in ATRP/ATRA are typically determined from model studies in which copper(I) complex is reacted with alkyl halide in the presence of radical trapping agents such as 2,2,6,6-tetramethylpiperidine-*N*-oxyl radical (TEMPO, see **Physical Properties of Thiazyl Radicals Toward Conductive and Magnetic Materials and Nitroxide-Mediated Polymerization and its Applications**).^{188–190} Rates are determined by monitoring the rate of disappearance of alkyl halide in the presence of a large excess of the activator (Cu(I)X/L) and TEMPO. Under such pseudo-first-order conditions, the activation rate constant can be calculated from $\ln([RX]_0/[RX]_t)$ versus t plots (slope = $-k_a[\text{Cu(I)C/L}]_0 t$). The activation rate constants are very dependent on the structures of the complexing ligand, initiator, and monomer. In a recent study of a variety of copper(I) complexes with nitrogen-based ligands, values of k_a were found to span more than six orders of magnitude.¹⁹¹ Representative examples are shown in Figure 4. Generally, the activation rate constant in ATRP/ATRA will depend on the topology of the complexing ligand (cyclic $\sim$ linear $<$ branched), nature of the N-ligand (aryl amine $<$ aryl imine $<$ alkyl amine $\sim$ pyridine), steric bulk around the metal center, and the linking unit between the nitrogen atoms ($\text{C4} \ll \text{C3} < \text{C2}$) or the “bite” angle. Compounds that contain halogen atoms activated by α -carbonyl, phenyl, vinyl, or cyano groups make efficient ATRP initiators (Figure 2). The reactivity of these initiators can be correlated with bond dissociation energy (BDE).¹⁹² The activation rate constant in ATRP (k_a) generally depends on (i) the degree of initiator substitution (primary $<$ secondary $<$ tertiary), (ii) the leaving atom/group ($\text{Cl} < \text{Br} < \text{I}$), and (iii) radical stabilizing groups ($-\text{Ph}-\text{C}(\text{O})\text{OR} \ll \text{CN}^-$). Representative examples are given in Figure 5. It was recently shown that the penultimate monomer unit can also have a strong effect on k_a .^{193,194} For example, k_a for dimeric alkyl halide H-MMA-MA-Br is approximately five times higher than for H-MA-MA-Br. This can be attributed to the back-strain effect. Furthermore, the rate of activation of a dormant chain end with an

Figure 4 Rate constant of activation (k_a in $\text{M}^{-1} \text{s}^{-1}$) for various ligands with ethyl 2-bromoisobutyrate (EBriB) in the presence of Cu(I)Br in CH_3CN at 35°C .¹⁹¹ [Reproduced from Ref. 64. With permission of Springer Science + Business Media.]

MMA–Br terminal unit is approximately 20 times higher than with a MA terminal unit containing the same penultimate unit. This effect is induced by the formation of the thermodynamically more stable 3° radical when compared to the less stable 2° radical. Lastly, the combined effects of back-strain and radical stability result in a ~ 100 -fold increase of k_a for H–MMA–MMA–Br.

Other investigations include the effect of solvent, counterion, temperature, ligand/catalyst ratio, presence of monomer, and copper(II) complexes on the activation rate constant.^{195–202}

4.3 Deactivation Rate Constants in ATRP

Deactivation rate constants (k_d) have been much less studied in ATRP. The principal reason is the lack of experimental techniques for measuring the relatively fast deactivation process. One of the methods includes the clock reaction (see **Radical Kinetics and Clocks**) in which the generated radicals are simultaneously trapped with TEMPO and the deactivator $\text{Cu(II)X}_2/\text{L}$

Table 2 Deactivation rate constants (k_d) for 1-phenylethyl radicals measured under various conditions at 75°C .¹⁸⁹

Complex	Solvent	k_d ($\text{M}^{-1} \text{s}^{-1}$)
$\text{Cu(II)Br}_2/\text{dNbpy}$	CH_3CN	2.5×10^7
$\text{Cu(II)Br}_2/\text{PMDETA}$	CH_3CN	6.1×10^7
$\text{Cu(II)Br}_2/\text{Me}_6\text{TREN}$	CH_3CN	1.4×10^7
$\text{Cu}^{\text{II}}\text{Br}_2/2\text{dNbpy}$	Ethyl acetate	2.4×10^8
$\text{Cu(II)Cl}_2/2\text{dNbpy}$	CH_3CN	4.3×10^6

complex (Scheme 11).¹⁸⁹ Results for 1-phenylethyl radicals generated by thermal decomposition of 1-(*N,N*-(2-methylpropyl-1)(1-deithylphosphono-2,2-dimethyl-propyl-1)-*N*-oxyl)-1-phenylethane (PESG1) alkoxyamine are summarized in Table 2. In the deactivation process, the $\text{Cu(II)Br}_2/\text{dNbpy}$ complex was more active in ethyl acetate than in acetonitrile. Deactivation was also slower with Cu(II)Cl_2 than Cu(II)Br_2 complexes.

Furthermore, $\text{Cu(II)Br}_2/\text{dNbpy}$ complex appeared to have higher activity than either $\text{Cu(II)Br}_2/\text{PMDETA}$ or $\text{Cu(II)Br}_2/\text{Me}_6\text{TREN}$.

Additionally, deactivation rate constants (k_d) for more active catalysts such as $\text{Cu(I)X}/\text{Me}_4\text{CYCLAM}$

Figure 5 Values of k_a ($\text{M}^{-1} \text{s}^{-1}$) for various initiators with Cu(I)X/PMDETA in CH_3CN at 35°C .¹⁹³

have been estimated from the initial degree of polymerization without reactivation, end functionality, and molecular weight distributions.^{200,203,204}

With recent advances in the determination of the equilibrium constant for atom transfer ($K_{\text{ATRP}} = k_a/k_d$), deactivation rate constants ($k_d = k_a/K_{\text{ATRP}}$) can now be easily obtained from readily accessible activation rate constants (k_a).¹⁸³ Figure 6a shows the

correlation of activation (k_a) and deactivation (k_d) rate constants with equilibrium constant (K_{ATRP}) for various Cu(I)Br/L complexes with EBrIB at 22°C in CH_3CN . The k_a values were extrapolated from those at 35°C .^{191,195} Generally, the equilibrium constant increases as a consequence of an increase in k_a accompanied by a decrease in k_d . Figure 6b indicates the trend with various initiators in the presence of Cu(I)/TPMA catalyst under identical reaction conditions. As is evident, the more reactive dormant species generate less reactive radicals (lower k_d); however, k_d is generally less dependent on K_{ATRP} for initiators than for complexing ligands.

4.4 Correlating Redox Potential with Equilibrium Constant for Atom Transfer

One approach to developing a greater understanding of the overall ATRP equilibrium is to examine the reactions that formally contribute to it. The equilibrium constant for atom transfer ($K_{\text{ATRP}} = k_a/k_d$) can be expressed as a combination of several contributing reversible reactions (Scheme 12)^{59,60}:

1. Electron transfer or oxidation of metal complex (K_{ET});
2. Electron affinity or reduction of halide radical to halide anion (K_{EA});
3. Bond homolysis of alkyl halide (K_{BH});
4. "Halophilicity" or association of halide anion to metal complex (K_{HALIDO}).

Generally, these equilibrium constants are very solvent-dependent. In particular, the values of K_{EA} are expected to be relatively high in protic solvents because halide anions can be stabilized through solvation in such media.²⁰⁵ Also, on the other hand, K_{HALIDO} values will be likewise affected with changes in solvent polarity.⁶⁰ Low values of K_{HALIDO} in polar and protic media have direct implications on the degree of polymerization control because of the decreased amounts of deactivator ($\text{Mt}^{n+1}\text{X/L}$), as a result of halide anion dissociation from the metal center.

Catalyst activity (in terms of K_{ATRP}) is also intrinsically dependent on the redox potential of the metal complex. The latter, in turn, depends on the relative stability of the higher (Mt^{n+1}/L) and lower (Mt^n/L) oxidation states. For the case of

Scheme 11 Model reactions for deactivation rate constant measurements.

Figure 6 Correlation of activation (k_a) and deactivation (k_d) rate constants with equilibrium constant (K_{ATRP}) for various Cu(I)Br/L complexes with (a) EBrIB as initiator and (b) various initiators with Cu(I)TPMA complex. (a) Ligands 1: Cyclam-B, 2: Me6TREN, 3: TPMA, 4: BPED, 5: TPEDA, 6: PMDETA, 7: BPMPA, 8: dNbpy, 9: HMTETA, 10: bpy, 11: N4[3,2,3], 12: N4[2,3,2]. (b) Initiators 1: McAc, 2: BzCl, 3: PECl, 4: MCIP, 5: EtClIB, 6: BzBr, 7: CIAN, 8: PEBr, 9: MBrP, 10: CIPN, 11: EtBrIB, 12: BrPN, 13: EBPA.

relatively stable 1:1 copper complexes, the redox potential can be calculated using the following equation^{206–210}:

$$\beta_k^m = \frac{[\text{Cu}^m \text{L}_k]}{[\text{Cu}^m][\text{L}]^k}; m = \text{I or II}$$

$$E \approx E^0 + \frac{RT}{F} \ln \frac{[\text{Cu(II)}]_{\text{total}}}{[\text{Cu(I)}]_{\text{total}}} - \frac{RT}{F} \ln \frac{\beta(\text{II})}{\beta(\text{I})} \quad (4)$$

The redox potential of the Cu(II)L/Cu(I)L couple is related to the equilibrium constant for electron transfer (K_{ET}) according to the equation

$$E = -\frac{RT}{F} \ln K_{ET} \quad (5)$$

As indicated in Scheme 12, for a given alkyl halide R–X, the activity of the catalyst in ATRP does not only depend on the redox potential but also on the “halidophilicity” of the metal complex

$$\frac{K_{\text{ATRP}}}{K_{\text{EA}}K_{\text{BH}}} = K_{\text{ET}}K_{\text{HALIDO}}$$

Scheme 12 Reactions formally contributing to the overall ATRP equilibrium.

Figure 7 A plot of K_{ATRP} versus $E_{1/2}$. K_{ATRP} values are reported for Cu(I)Br/L complexes and ethyl 2-bromoisobutyrate, and $E_{1/2}$ was measured relative to standard calomel electrode (SCE) (solvent = CH_3CN , $T = 22^\circ\text{C}$).^{183,211,212}

(K_X). Both parameters are affected by the nature of transition metal and complexing ligand (including binding constants, basicity, back bonding, etc). For complexes that have similar “halidophilicities,” the redox potential can be used as a measure of catalyst activity in ATRP. This was demonstrated in the linear correlation between K_{ATRP} and $E_{1/2}$ values for

a series of copper(I) complexes with nitrogen-based ligands (Figure 7).^{183,211,212}

4.5 Radical Nature of Propagating Species

On the basis of several experimental evidences and observations, TMC ATRP is a radical process. Chemoselectivity,²¹³ cross-propagation kinetics,²¹⁴ kinetic isotope effects,²¹⁵ the reactivity ratios,^{214,216–220} and regio- and stereoselectivity^{65,217,221,222} are similar to those of free-radical polymerizations. ATRP is initially retarded in the presence of small amounts of oxygen or free-radical inhibitors, such as galvinoxyl or TEMPO, which directly react with a growing radical and inhibit chain growth by terminating the polymerization.²²³ Furthermore, ATRP can be conducted in the presence of water or other protic solvents, and is tolerant to a wide variety of functionalities present in the (co)monomers.^{224,225} Cross-exchange between different halogens²²⁶ and different polymerization systems (thermal and ATRP or nitroxide-mediated polymerization and ATRP) demonstrates that these reactions have the same intermediates and supports a common radical mechanism.²²⁷ ATRP can be converted to a system that displays conventional radical polymerization by the addition of octanethiol as a chain transfer reagent.²²⁸ Chain transfer in *n*-butyl acrylate polymerization also resembles the conventional radical

Figure 8 Comparison of free energies during an ISET and concerted OSET process for the reaction of bromoacetonitrile with Cu(I)/TPMA complex in CH₃CN at 25 °C. [Reproduced with permission from Ref. 237. Copyright 2008 American Chemical Society.]

process.²²⁹ Lastly, racemization studies using optically active alkyl halides,²²³ direct observation of deactivator species (transition metal complexes in the higher oxidation state, i.e., Cu(II))^{230–235} and propagating free radicals in the polymerization of dimethylacrylates²³⁶ by EPR also supports radical mechanism.

Mechanistically, atom transfer radical process could occur either via the outer-sphere electron transfer (OSET) or via inner-sphere electron transfer (ISET), that is, atom transfer passing through a Cu–X–C transition state, which is formally also a single-electron transfer process. OSET can proceed in a stepwise manner with radical anion intermediates or in a concerted process with simultaneous dissociation of alkyl halide to a radical and anion. According to the Marcus analysis of electron transfer processes, OSET should have an energy barrier approximately 15 kcal mol^{−1} higher than what was experimentally measured.²³⁷ In other words, OSET should be approximately 10¹⁰ times slower than experimentally measured values. The results clearly indicate that the differences between energy barriers for ISET and OSET are much greater than any computational or experimental errors, and it can therefore be concluded that the mechanism of ATRP occurs via a copper-catalyzed concerted homolytic dissociation of an alkyl halide. Additionally, the one-step dissociative electron

transfer to form a radical and an anion is energetically more favorable than the two-step process via the radical anion intermediates. The free-energy profiles of computational analysis of the reaction of Cu(I)/TPMA complex with bromoacetonitrile in CH₃CN at 25 °C are shown in Figure 8.

5 CONTROL OF POLYMER COMPOSITION

As mentioned previously, ATRP is particularly suited for the synthesis of well-defined (co)polymers. The spectrum of (co)polymers that can be prepared by a well-controlled ATRP includes polymers with virtually any desired distribution of monomer units along the polymer backbone, or within any specific segment in a copolymer. This includes homopolymers as well as random, alternating, gradient, block, graft, brush, and star copolymers (Figure 9).⁶³ Each type is discussed in detail in the following sections.

5.1 Well-Defined Homopolymers

Copper-catalyzed ATRP is particularly suitable for homopolymerization of a wide variety of monomers (Scheme 7) that contain an α -stabilizing substituent

Figure 9 Composition of (co)polymers synthesized using ATRP.

adjacent to the transferable atom or group in order that the dormant chain end can be reactivated. Therefore, simple α -olefins cannot be easily homopolymerized. However, they can be copolymerized with highly active monomers such as acrylates. With acidic monomers, carefully chosen reaction conditions are needed in order to minimize protonation of nitrogen-based complexing ligands, which leads to diminished catalytic activity. Potential solutions are to utilize protected groups (acetal, *t*-butyl ester) or anionic forms (sodium salt or protonated tertiary amines).

Monomers/polymers that can complex copper species (amides, polyamines, or some proteins) can displace ligands and deactivate catalysts unless the stability constants are large enough (e.g., for TPMA). Finally, monomers containing groups that easily participate in radical transfer, such as thiols, cannot be used directly in ATRP and should be protected. The major difference between the polymers prepared by ATRP and prior art polymers prepared by free-radical polymerization are the additional degrees of control over architecture, molecular weight, molecular weight distribution, and telechelic functionality.⁴⁷

5.2 Well-Defined Copolymers

5.2.1 Copolymers with Controlled Molecular Weight

One of the main advantages of TMC ATRP is the ability to control molecular weight and molecular

weight distribution of copolymers containing functional monomers. Control over molecular weight requires efficient initiation and preservation of activity in the majority of the polymeric chains. However, termination and other side reactions are also present in ATRP, and they usually become more prominent as higher molecular weight polymers are targeted. For example, in copper-mediated ATRP of styrene, a slow termination process was observed, mainly arising from the interaction of the copper(II) species with both the growing radical and the macromolecular alkyl halide.²³⁸ The catalytic species can participate in the OSET reactions by either oxidation of the polystyryl radicals to carbocations or reduction of radicals to carbanions via reactions with copper(II) and copper(I) species. Studies with model compounds and macromolecular polystyrene species have demonstrated that the elimination reaction was accelerated in the presence of the copper(II) complex. This process limited the molecular weight of the resulting homopolymers.^{238,239} However, these prior limitations on the maximum molecular weight of the (co)polymers that can be prepared by ATRP have been surmounted by the development of ARGET ATRP which minimizes OSET catalyst-based oxidation or reduction reactions,^{240,241} allowing the synthesis of high molecular weight polymers such as styrene acrylonitrile (SAN)²⁴² copolymers and polyacrylonitrile (PAN) with less apparent tailing ($M_n \sim 200\,000 \text{ g mol}^{-1}$ and $M_w/M_n \sim 1.2$).²⁴³ A recent extension of ARGET ATRP was also demonstrated in preparation of poly(methyl methacrylate)

with molecular weight as high as $1\,000\,000\text{ g mol}^{-1}$ using a dithioester initiator.^{244,245}

Another approach to high molecular weight polymers is conducting ATRP under elevated pressure. At high pressures, the propagation rate constant is enhanced and that of the termination suppressed, thereby resulting in a higher ratio of k_p/k_t . For example, at 6 kbar pressure, polystyrene with $M_n = 1\,000\,000\text{ g mol}^{-1}$ and $M_w/M_n = 1.24$ and PMMA with $M_n = 1\,200\,000\text{ g mol}^{-1}$ and $M_w/M_n = 1.17$ were synthesized at room temperature within a few hours with targeted molecular weight.^{246,247}

5.2.2 Statistical and Gradient Linear Copolymers

Reactivity ratios in ATRP are the same as in radical polymerization, although small differences exist that have been ascribed to nonequilibrated systems.^{248,249} In contrast to conventional free-radical copolymerization, where differences in comonomer reactivity ratios result in a variation in copolymer composition, in CRP this variation in instantaneous incorporation of the monomers into the copolymer results in a tapering in composition along the main chain of the copolymer.^{250,251} Gradient copolymers can be prepared by either simultaneous copolymerization of monomers with different reactivity ratios (spontaneous gradient) or by continuous feeding of one monomer (forced gradient).^{218,252} The shape of the gradient depends on the concentration of comonomers, their reactivity ratios, and the feeding process. In a mini-emulsion, it also depends on the comonomer's solubility.^{253,254} Gradients can be linear, V-shaped, or curved. Gradient may reflect not only the density of grafting or composition but also the stereostructure.²⁵⁵

5.2.3 Alternating Copolymers

Alternating copolymers are the simplest periodic copolymers. There are several comonomer pairs that copolymerize in alternating fashion by ATRP. They include strong electron donors and strong electron acceptors, for example, styrene-maleimides.²⁵⁶ It is also possible to use one kinetically reactive but thermodynamically non-homopolymerizable monomer.

Another possibility is to use a less reactive monomer in large excess. In such a way, nearly alternating copolymers of acrylates with olefins have been prepared.^{89,257} The reactivity ratios of the monomers can also be affected by complexation. For example, in the presence of strong Lewis acids, methyl methacrylate tends to form alternating copolymers with styrene.²⁵⁸ For some imers with a reactive alkyl halide but unreactive alkene, a polyaddition is possible that generates a new polymer structure with a heteroatom in the main chain.^{259,260}

5.2.4 Linear Segmented Copolymers (Block and Multisegmented)

The area of segmented copolymers is perhaps the most prolific in ATRP. The end groups of polymers prepared by other techniques, including cationic, anionic, coordination, and step-growth polymerization, were converted to ATRP-initiating sites and used directly as macroinitiators for ATRP.

Efficient block copolymerization requires an appropriate sequence of blocks. This order generally follows radical stabilities and can be correlated with the proportion of the active species. This order may be specific for a particular polymerization. In ATRP, the order is as follows: acrylonitrile > methacrylates > styrene ~ acrylates > acrylamides. In ATRP, the block order can be altered by using halogen exchange. This way, thermoplastic elastomers of PMMA-PBA-PMMA were successfully obtained by starting from Br-PBA-Br and using CuCl/L to extend the chain with MMA.^{110,261–263} ABC, ABCD, and ABCBA blocks were also prepared by ATRP.²⁶⁴

ATRP macroinitiators were successfully converted to reverse addition-fragmentation chain transfer (RAFT) (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications** and NMP see **Nitroxide-Mediated Polymerization and its Applications**) initiators. After site transformation, these macroinitiators served as a starting point for RAFT- and NMP-mediated block copolymerization.²⁵¹ Dual initiators could also be used for a successive ATRP and RAFT polymerization,²⁶⁵ and other techniques.^{266,267}

The dormant species in styrene cationic polymerizations and ATRP systems have identical

structure. Therefore, Cl-terminated polystyrenes from cationic polymerization could be efficiently extended via ATRP with polystyrene and also with poly(meth)acrylates.¹⁰⁸ ATRP was initiated by acetal end-functionalized alkyl halides which were subsequently used to grow vinyl ethers by living cationic polymerization. The reverse process was also successful owing to the high tolerance of cationic polymerization of vinyl ethers to impurities.²⁶⁸ Living carbanions were quenched by species serving as initiators for ATRP, and subsequently chain-extended.²⁶⁹ Cationic polymerization of tetrahydrofuran (THF) was initiated by 2-bromoisobutryl bromide and silver triflate. The subsequent addition of ATRP catalyst allowed the controlled polymerization of MMA, n-butyl acrylate (BA), and styrene from the residual bromoester moiety.²³² Bromo-end groups in ATRP of styrene were used to directly initiate ring-opening polymerization of oxazolines.²⁷⁰ Hydroxy end groups in polymers from anionic ring-opening polymerization (AROP) of ethylene oxide or lactones were directly esterified to bromoesters and used as ATRP initiators. 2-Hydroxyethyl 2'-bromoisobutyrate is a simple dual initiator capable of initiating both AROP and ATRP.²⁷¹ Depending on the initiating/catalytic systems, the rates of both processes can be comparable, allowing the simultaneous presence of two noninterfering processes.^{272,273}

Unsaturated chain ends in polyethylene and polypropylene were transformed to bromoesters to initiate ATRP of styrene and (meth)acrylates. Hydroxy functional polyethylene obtained in degenerative transfer polymerization of ethylene was used in a similar way for block copolymerization via ATRP.^{274–277} A similar approach was used to create graft copolymers. Copolymerization of ethylene and 10-undecen-1-ol in the presence of a trialkylaluminum protecting group can be conducted with a metallocene catalyst. The hydroxyl functionality was converted into an α -bromoisobutyrate functionality, and the resulting polyethylene multifunctional macroinitiator was used for a “grafting-from” ATRP procedure. In this way, copolymers such as polyethylene-*g*-poly(methyl methacrylate) have been produced which act as compatibilizers for otherwise immiscible polymers.^{276,278,279}

Several methods combine CRP with ROMP. Molybdenum alkylidene chain ends are destroyed by aldehydes. Thus, aldehydes with activated alkyl

bromides were used to terminate ROMP of norbornene and subsequently form block copolymers with styrene and (meth)acrylates.²⁸⁰ Another interesting possibility is the simultaneous growth of polymer chains via ROMP on ruthenium alkylidenes which also serve as ATRP catalysts. Interestingly, an excess of phosphines reduces the rate of ROMP, but does not affect the rate of ATRP.^{150,281}

End groups from many step-growth polymers are easily transformed to ATRP macroinitiators. Thus, terminal hydroxy groups from polyesters, polycarbonates, or polysulfones were esterified to bromoesters and subsequently chain-extended with styrene or (meth)acrylates.^{109,282,283} Polythiophenes are formed by polycondensation, but the mechanism follows a chain-growth rather than a step-growth process. It is therefore possible to prepare polythiophenes with low polydispersity. End groups are well controlled and can be converted to ATRP initiators. Block copolymerizations with this technique have been very efficient, and well-defined nanostructured materials have been prepared.^{284–287}

CRP was also combined with polymers prepared by conventional radical polymerization. For example, telechelic polymers prepared by radical polymerization can either contain ATRP-active sites or can be converted to the corresponding macroinitiators and used for controlled ATRP. In such a way, poly(vinyl acetate) was block copolymerized with styrene and acrylates. Conversely, well-defined blocks were used to initiate uncontrolled radical polymerization of vinyl acetate to afford another type of block copolymer.²⁸⁸

Multisegmented block copolymers are typically prepared by polycondensation processes. ATRP can be used to make ABC or ABCBA segments by sequential polymerization. However, chain coupling can afford multisegmented copolymers in a much simpler way. Such coupling can be done with termination by radical coupling; however, yields in these reactions are rather low. Another approach involves click chemistry. An ATRP initiator with an acetylene functionality (such as propargyl 2-bromoisobutyrate) was used to synthesize an α -alkyne- ω -bromo-terminated block copolymer which was further reacted with NaN_3 to generate the corresponding α -alkyne- ω -azido-terminated block copolymer. This functional diblock was then click-coupled in a step-growth process at room temperature in the presence of Cu(I) to generate segmented block copolymers (Scheme 13).^{289,290}

Scheme 13 Segmented block copolymers synthesized using a combination of ATRP and “click” chemistry.

Scheme 14 Stereoblock poly(atactic-dimethylacrylamide)-*b*-poly(isotactic-dimethylacrylamide).

5.2.5 Stereoblock Copolymers

Radical polymerization is not stereoselective (see **Stereoselective Radical Reactions**). However, in the presence of some complexing agents that strongly interact with the pendent groups of the polymer chain end and/or the monomer, the proportion of syndiotactic or isotactic triads can be significantly increased. This has been demonstrated for the polymerization of acrylamides in the presence of catalytic amounts of $\text{Yb}(\text{OTf})_3$ or $\text{Y}(\text{OTf})_3$ ²⁹¹ and also in the polymerization of vinyl esters in fluoroalcohols.²⁹² ATRP offers the special advantage that atactic segments formed without complexing agent can be extended with regular blocks formed in the presence of such agents. In such a way, stereoblock poly(atactic-dimethylacrylamide)-*b*-poly(isotactic-dimethylacrylamide) was formed (Scheme 14).^{293–295} An interesting extension of this approach was applied to prepare stereo-gradient copolymers.²⁵⁵

conditions. There are many initiators and macroinitiators that contain functional group(s) and therefore add value to the obtained products.^{47,250} Several difunctional activated alkyl halides are commercially available. Many others can be prepared by simple esterification of diols and functional alcohols with, for example, 2-bromoisobutyryl bromide.

6.2 Star Polymers

Star polymers can generally be prepared using four different approaches.²⁹⁶ Multifunctional initiators can be used to simultaneously grow several arms via a core-first approach (left part of Scheme 15). Polyols were converted to the ATRP initiating core with 3, 4, 6, 12, or more initiating sites.^{297–299} Core was also prepared by cross-linking the divinyl compound under high dilution.³⁰⁰ The synthesis of star-like structures by CRP using a core-first method faces the danger of potential cross-linking and gelation because of radical coupling. Thus, a relatively low concentration of radicals and low conversions are often used to minimize star–star coupling.

An arm-first approach involves attachment of chains to a functional core (right part of Scheme 15). Linear monofunctional Br-terminated chains formed by ATRP were converted to azides and subsequently “clicked” to a core with several acetylene groups.³⁰¹

Another approach utilizes arms that are cross-linked in the presence of divinyl compounds (Scheme 16). In this case, the number of arms in the resulting stars is not precisely controlled. Also, star–star coupling between the

6 POLYMER TOPOLOGY BY ATRP

6.1 Linear Chains

ATRP was successfully used in the synthesis of linear chains in the range $M_n > 1$ million. The use of difunctional initiators allowed, for the first time in a radical process, simultaneous two-directional chain growth. This gives access to functional telechelic polymers and polymers with molecular weights twice larger than otherwise attainable under similar

Scheme 15 Approaches used for the synthesis of star copolymers.

Scheme 16 Synthesis of stars by crosslinking of arms in the presence of divinyl compounds.

cores may occur. This synthetic procedure requires precise manipulation of arm length, the amount of divinyl compound, and the reaction time.^{302–304} A cross-linker can be added to isolated arms or at a certain moment during the arm synthesis, allowing for control of the core density. All of these parameters affect the resulting star structure. As an example, the synthesis of stars with ~50 arms in >90% yield will require ~10-fold molar excess of crosslinker (vs. arm end groups) for precursors with DP ~100. Stars in even higher yield (>98%) and with lower PDI (<1.2) can be prepared by replacing macroinitiators with macromonomers. In that case, R in the monomer is a macromolecular substituent and the initiator is used under substoichiometric conditions (Scheme 16).³⁰⁵

Stars prepared via the arm-first process still contain active/dormant species at the core. Thus, they can be used to grow a second generation of arms by the so-called in-out approach. Such

mikto-arm stars can contain the same monomeric units but can be of different lengths; they can also contain hetero-arms. The efficiency of reinitiation is often low owing to the poor accessibility of the monomer/catalyst to the sterically congested core, but may also result from enhanced termination inside the core. By using a degradable cross-linker with an S–S linking unit, it was determined that efficiency of reinitiation is usually ~30%.^{304,306} The vinyl and/or halide residual functionalities were used for further core functionalization.³⁰⁷

6.3 Comb and Graft Copolymers

Comb-like polymers can be prepared using techniques similar to those described for stars.^{250,308} However, instead of a compact core, a long, linear backbone was employed. These three techniques correspond to grafting-from, -onto, and -through.

Scheme 17 Synthesis of branched polymers using ATRP.

Interesting brush topologies³⁰⁹ with unique properties were prepared using different macro-monomers in heterografted brush copolymers³¹⁰ or block brush copolymers prepared by a combination of grafting-from and grafting-through.³¹¹ When macro-monomers are polymerized by grafting from a macroinitiator, double-grafted brush copolymers can be synthesized where each graft is a brush.³¹²

the concentration of deactivator. Copolymerization of inimers with regular monomers reduces the degree of branching and increases the branch length.³¹⁶

Hyperbranched structures can also be obtained when divinyl monomers are copolymerized in small amounts or in the presence of chain transfer compounds (thiols)³¹⁷ or ATRP initiators that favor the formation of branched products.^{318,319}

6.4 Branched and Hyperbranched Polymers

ATRP was used to prepare hyperbranched polymers.^{313–315} Monomers that also serve as initiators (so-called inimers) were successfully used to make such materials (Scheme 17). The ratio of reactivities of the initiating site and the active species resulting from the alkene moiety define the degree of branching (which can approach 50%). It is possible to additionally affect this ratio by varying

6.5 Dendritic Structures

While hyperbranched systems are irregular, branching is well controlled in dendritic structures. Dendritic structures have been prepared by ATRP alone or by combinations with other controlled living polymerization techniques.^{320–322} Polymer chains were grafted from dendrimers or attached to dendrimers. Single chains were combined with

dendrimer structures, and dendrons were also functionalized with methacrylate groups and copolymerized to form stiff polymer chains.^{323–326}

6.6 Polymer Networks and Microgels

Most polymer networks have irregular structures. However, ATRP can significantly improve network uniformity. When a divinyl compound is copolymerized with a monovinyl compound, the gel point in ATRP occurs much later than in radical polymerization. This is due to the fact that, in ATRP, only short chains are formed at the early stages and the number of pendant double bonds in each chain is much lower than in conventional radical polymerization.³²⁷ The gel point depends on the ratio of cross-linker to initiator and generally requires the ratio to exceed unity for moderate intramolecular cyclization. However, gel point depends also on the moment of cross-linker addition, initiation efficiency, monomer reactivity, chain polydispersity, and other parameters.^{319,328} Gels prepared by ATRP have generally a much higher swelling ratio than those made by conventional radical polymerization.^{318,327,329} Degradable gels were prepared by the copolymerization of styrene or methyl methacrylate and a disulfide-containing difunctional methacrylate.^{330,331} It is also possible to use cross-linkers that can be reversibly cleaved, which leads to the formation of reversible gels.^{168,304}

6.7 Cyclic Polymers

CRP has no special advantage in forming cyclic polymers. Rather, anionic and/or cationic polymerizations are better suited to make cyclics by using complementary reagents at very low concentrations. However, cyclization has been reported when click chemistry was used in a reaction of azido- and acetylene-terminated chains.^{289,332}

6.8 Molecular Hybrids

Molecular hybrids comprise synthetic polymers attached covalently to inorganic materials

and to natural products.^{333,334} The well-defined organic–inorganic hybrids can be formed by grafting from flat, convex, concave, or irregular surfaces.^{114,335} Surfaces of gold, silicon, silica, iron, and other inorganic substrates were functionalized with bromoesters to initiate the growth of polystyrene, poly(meth)acrylates, polyacrylonitrile, or polyacrylamide chains via ATRP.³³⁶ It is possible to vary the grafting density and prepare very densely grafted films, with density approaching ~ 0.5 to 1 chain per square nanometer.^{337,338} Grafting density could be continuously varied along the substrate to prepare surfaces with a macroscopic gradient.³³⁹ Very dense grafting is not possible via grafting onto, since the attached polymer chains collapse on the surface and prevent other chains from the solution from reaching the surface. Nonuniform growth cannot provide a high grafting density. Only when polymer chains grow by adding “a few monomer units at a time” is high grafting density possible. The resulting hybrids have many new and unusual properties related to their unique compressibility, lubrication, swelling, or interpenetration.³³⁸ Grafting can be performed by normal ATRP and also by ARGET.¹⁷³

It is also possible to graft polymers and block copolymers onto inorganic surfaces. For example, poly(methacrylic acid)-*b*-poly(methyl methacrylate)-*b*-poly(sodium styrenesulfonate) prepared by ATRP was grafted onto ~ 200 -nm diameter iron particles to destroy residual chlorinated pollutants.³⁴⁰

Slower chain growth in ATRP facilitates better control in templated systems. Mesoporous silica was functionalized with bromoesters and used to grow polyacrylonitrile, polystyrene, or poly(meth)acrylates. Growth of polymer chains was followed by thermogravimetric analysis (TGA), porosity measurements, and analysis of detached polymers. Highly uniform growth was achieved on the molecular level (as evidenced by low polydispersity of detached polymers analyzed by gel permeation chromatography (GPC) but also macroscopically (overall porosity measurements). The resulting polyacrylonitrile was converted to very regular nanosize carbon filaments ($D \sim 10$ nm, $L > 1 \mu\text{m}$, $S = 840 \text{ m}^2 \text{ g}^{-1}$; Scheme 18).^{114,341,342}

Functional groups in natural products have been converted to ATRP initiators (NH_2 or OH groups converted to bromoamides and bromoesters).^{113,334,343} During polymerization, the

Scheme 18 Synthesis of nanosize carbon filaments.

Figure 10 Multifunctional polymers prepared using ATRP/CRP techniques.

original substrate should not interfere with the ATRP process and the functionality and properties of the natural products should not be destroyed by ATRP. Alternatively, chains prepared by CRP-containing functionalities (NH_2 or OH) were used to grow polypeptides or DNA. It is also possible to fuse functionalized natural products and organic polymers together with click reactions, by biotin–avidin chemistry, or from genetically modified peptides.^{334, 344–357}

7 FUNCTIONAL POLYMERS

Radical polymerization is tolerant to many polar groups such as $-\text{OH}$, $-\text{NH}_2$, or $-\text{COOH}$ and can be carried out in water. In CRP, functionalities can be incorporated into specific parts of polymer chains, as shown in Figure 10.⁴⁷

Functional monomers were directly incorporated into polymer backbones, as well as in a protected form. For example, 2-hydroxyethyl (meth)acrylate was homopolymerized and copolymerized by ATRP.^{77,79} Also, trimethylsilyl (TMS) derivatives were polymerized and subsequently deprotected. The hydroxy groups were then functionalized with 2-bromopropionate groups and extended to form densely grafted molecular brushes.^{79,110}

End groups can be incorporated either by using functional initiators or by converting the growing chain ends to another functional group.⁴⁷

Functional initiators allow the introduction of functionality to only one chain end. Various functionalized ATRP initiators were used to prepare hetero-telechelic polymers.⁴⁷ Additionally, atom transfer radical coupling enables the efficient coupling of chains and provides a route to telechelic polystyrenes.³⁵⁸ Atom transfer radical coupling is less efficient for methacrylates (the growing radicals predominantly disproportionate rather than couple) and for acrylates (too low an equilibrium constant). However, it is sufficient to add a few styrene units at the acrylate chain end to successfully form polyacrylate telechelics. Multifunctional star polymers were prepared from functional macroinitiators.

The dormant chain end in all CRP processes can be further converted to other functional groups by radical or nonradical processes. For example, dithioesters in RAFT (see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**) were converted to thiols, the alkoxyamines in NMP (see **Nitroxide-Mediated Polymerization and its Applications**) to alkyl chlorides, and the alkyl halides in ATRP to allyl, hydroxy, amino, azido, and ammonium or phosphonium groups in excellent yields. It is also possible to incorporate one functional monomer at the chain end if the monomer is much less reactive and forms an unreactive dormant species.

Scheme 19 Post-polymerization functionalization of ω -telechelic transferable atoms.

Scheme 19 presents three types of reactions employed for end-functionalization of ATRP polymers: nucleophilic substitution, electrophilic substitution, and in stars to multifunctional polymers. A similar approach was applied to hyper-branched polymers prepared by (co)polymerization of inimers.

8 APPLICATIONS

8.1 Applications of Materials Prepared by ATRP

Block copolymers based on acrylates and other polar monomers find applications as polar thermoplastic elastomers²⁶² in automotive applications, as they do not swell in hydrocarbons. However, they can also be used for much more sophisticated applications such as controlled drug release in cardiovascular stents.³⁵⁹ Amphiphilic block copolymers with water-soluble segments have been successfully used as very efficient surfactants³⁶⁰ and

were also used for higher end applications including pigment dispersants,^{361,362} various additives, and components of health and beauty products. Segmented copolymers with nanostructured morphologies are promising as microelectronic devices.^{285,363}

Graft copolymers have been used as compatibilizers for polymer blends and may be used in many applications described for block copolymers.²⁷⁶ Gradient copolymers hold great promise in applications ranging from surfactants to noise and vibration dampening materials.^{218,364,365}

Designed branching allows precise control over melt viscosity and polymer processing. Such polymers (as well as comb and star polymers) can be used as viscosity modifiers and lubricants.³⁶⁶

An ultimate example of controlled topology might be a macromolecular bottle-brush.³⁰⁹ Such polymers, when lightly cross-linked, result in super-soft elastomers.³⁶⁷ Materials were synthesized with moduli ~ 1 kPa, which is in the range attainable by hydrogels. However, hydrogels must be swollen 100 times by water to reach such low moduli. Molecular brushes are swollen by their own short side chains that never leach. Thus, applications are foreseen ranging from intraocular lenses and other

biomedical applications requiring a soft material that does not leach to the surrounding tissue to electronic applications requiring the protection of delicate components by a soft solid. These materials also show very high ionic conductivities reaching 1 ms cm^{-1} for Li cations at room temperature.³⁶⁸ Brushes can be also used as core-shell cylindrical templates to prepare various nanostructured materials.^{369,370}

ATRP offers unprecedented control over chain end functionality. End functional polyacrylates are excellent components of sealants for out-door and automotive applications.^{53,371} Multifunctional low molecular weight polymers are desirable components in coatings with a low organic solvent content important for volatile organic compound (VOC) reduction.³⁷² It is also possible to design systems with two types of functionalities, curable by two independent mechanisms. Incorporation of degradable units into the backbone of vinyl polymers allows controlled cleavage and degradation/recycling of such polymers.

Molecular hybrids with a covalent attachment of well-defined functional polymer to either an inorganic component or a natural product are currently being extensively investigated and should lead to numerous materials with previously unattainable properties. Such hybrids allow better dispersability of inorganic components (pigments, carbon black, carbon nanotubes, nanoparticles), they dramatically enhance the stability of such dispersions, and they allow the formation of molecular nanocomposites. Also, dense polymer layers improve lubrication, prevent corrosion, and facilitate surface patterning. Precise grafting from chromatographic packing enables enhanced chromatographic resolution of oligopeptides and synthetic prions.³⁷³

Other potential applications include microelectronics, microfluidics, and optoelectronics, as well as biomedical applications such as components of tissue and bone engineering, controlled drug release and drug targeting, antimicrobial surfaces,³⁷⁴ steering enzyme activity,^{334,356,375–377} and many others.

However, it is very interesting to note that most recent developments in ATRP that allowed significantly diminish concentration of transition-metal catalysts have been adopted to ATRA and ATRC processes. Thus, although originally ATRA provided guidelines for ATRP, the cycle closed by passing the most recent developments in ATRP to ATRA.

The last section covers the most recent progress in transition-metal-mediated (TMC) ATRA and ATRP processes inspired by ARGET and ICAR ATRP systems.

8.2 ATRA and ATRC via ICAR and ARGET Processes

TMC ATRA and ATRC reactions are very versatile tools for the synthesis of small organic molecules starting from alkyl halides and alkenes.^{4,16,17,37,39,120,179,378} However, these methods for carbon-carbon bond formation are still not fully utilized in free-radical synthesis, and are by far much less represented in the literature than standard tin hydride-mediated radical addition to alkenes (see **Tin Hydrides and Functional Group Transformations**)³⁷⁹ and iodine atom transfer (see **Synthetic Radical Photochemistry**) radical reactions.³⁸⁰ The principal reason for small participation of TMC ATRA and ATRC reactions in organic synthesis until recently was the large amount of metal catalyst needed to achieve high selectivity of the desired monoadduct (typically between 5 and 30 mol% relative to substrate). Such large amounts of catalyst were required in these transformations in order to compensate for the accumulation of the deactivator or transition-metal complex in the higher oxidation state, as a result of unavoidable and often diffusion controlled radical-radical termination reactions ($k_t \approx 2.0 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$).

Until recently, the relatively high amount of transition-metal catalysts in ATRA made this methodology rather unsuitable for fine-chemicals synthesis because of the lengthy procedures needed to remove the catalyst from the reaction mixture. Also, on the other hand, the process was generally considered non-atom-economic because it required a relatively large excess of alkyl halide, was environmentally unfriendly, and was expensive. From the early stages, researchers have recognized these limitations of TMC ATRA, and various methodologies have been developed to overcome these problems. In particular, catalyst removal in TMC ATRA was addressed through the design of solid-supported catalysts,^{17,381,382} as well as the use of biphasic systems containing fluorosolvents.^{383–386}

Additionally, particularly in the case of copper, various highly active nitrogen-based complexing ligands have been developed that enable homogeneous ATRA reactions to be conducted using much smaller amounts of metal.^{59,387}

However, by far the most attractive method that solves the above issues in TMC ATRA reactions involves catalyst regeneration in the presence of environmentally benign reducing agents.^{120,165,170,171,174,178,388} This methodology was originally developed for mechanistically similar ATRP in processes termed ICAR and ARGET ATRP.^{44,120,165,167,170–174} Both processes were already illustrated in Scheme 10 (see below). Subsequently, this methodology was first applied to ATRA reactions catalyzed by ruthenium³⁸⁸ and then copper.¹⁷⁸ In all of these processes, the activator (transition-metal complex in the lower oxidation state) is continuously regenerated from deactivator (transition-metal complex in the higher oxidation state) in the presence of reducing agents such as phenols, glucose, ascorbic acid, hydrazine, tin(II) 2-ethylhexanoate, magnesium, and free-radical initiators. Such regeneration compensates for unavoidable radical termination reactions, enabling a significant reduction in the amount of metal catalyst. When applied to ATRA of CCl_4 to alkenes catalyzed by $\text{Cp}^*\text{Ru(III)Cl}_2(\text{PPh}_3)$ complex in the presence of AIBN, turn-over numbers (TONs) as high as 44 500 were obtained.³⁸⁸ Even more impressive TONs were achieved with CBr_4 and $[\text{Cu(II)(TPMA)Br}][\text{Br}]$ (TPMA = tris(2-pyridylmethyl)amine) complex (as high as 160 000), enabling efficient ATRA reactions in the presence of as low as 5 ppm of copper.¹⁷⁷ Previous TONs for copper-catalyzed ATRA ranged between 0.1 and 10.^{17,120} Since the initial reports by our group¹⁷⁸ and the research group of Severin,³⁸⁸ this method of catalyst regeneration in ATRA has been utilized in a series of organic transformations, with particular emphasis on detailed structural and mechanistic understanding of this process.^{39,40,120,175,180,181,377,389–411} This, in turn, could be a clear indicator that this methodology is on a potential trajectory to become a “greener” alternative to currently available synthetic processes for such organic transformations.^{39,120,179} The following sections describe recent synthetic applications of this novel catalytic system.

8.2.1 Highly Efficient TMC ATRC Reactions in the Presence of Reducing Agents

The methodology used to regenerate activator in ATRA originally developed for Ru^{388} and $\text{Cu}^{177,178}$ catalysts has been successfully utilized in a range of 5-exo-trig and 5-exo-dig ATRC reactions of bromoacetamides using 0.1–1 mol% of Cu(I)(TPMA)Br or $[\text{Cu(II)(TPMA)Br}][\text{Br}]$ complexes (Table 3).³⁹⁷ The presence of AIBN as a reducing agent enabled a 30–300-fold reduction in the amount of catalyst previously reported for such cyclizations.^{17,382,412–415} In a related study, $[\text{Cp}^*\text{Ru(III)Cl}_2(\text{PPh}_3)]$ complex, in conjunction with magnesium as a reducing agent, was also shown to be effective in ATRC reactions, producing lactones, lactams, and furans in excellent yields (Table 4).³⁹⁵ *N*-Allyldichloroacetamides are generally considered less reactive substrates for ATRC and, when standard catalysts such as Cu(I)Cl/bpy^{416} ($\text{bpy} = 2,2'$ -bipyridine) or $[\text{RuCl}_2(\text{PPh}_3)_3]^{417}$ are used, high catalyst loadings and/or elevated reaction temperatures are required. Although some ruthenium catalysts have been reported to catalyze ATRC reactions with these substrates at ambient temperatures and relatively low catalyst loadings, the main drawback of these complexes is their high air and moisture sensitivity.^{416,418} As indicated in Table 4, *N*-allyl-*N*-tosyldichloroacetamide successfully undergoes ATRC using as low as 5 mol% of air-stable $[\text{Cp}^*\text{Ru(III)Cl}_2(\text{PPh}_3)]$ complex, in combination with Mg, yielding 94% of the corresponding γ -butyrolactam after 4 hours at room temperature. The 5-endo cyclization reaction of α -bromo enamides has been investigated by Clark *et al.*^{17,381,413,414} Tertiary bromo enamides can be cyclized at room temperature using 30 mol% of $\text{Cu(I)Br/Me}_6\text{TREN}$ complex ($\text{Me}_6\text{TREN} = \text{tris}[2-(N,N\text{-dimethylamino})\text{ethyl}]\text{amine}$) in a reaction that proceeds through a radical–polar crossover mechanism with elimination of HBr .⁴¹³ Using the same ruthenium complex and Mg, instead of $\text{Cu(I)Br/Me}_6\text{TREN}$, the catalyst concentration can be reduced to 0.05 mol% without compromising the yield of the reaction (Table 4).

The last two examples in Table 4 indicate that Mg is also an effective reducing agent in ruthenium-catalyzed ATRC reactions of ethers and dichloroesters. The ATRC of 2,2,2-trichloroethyl ethers has been previously studied by Ram and

Charles.⁴¹⁹ However, efficient cyclizations were achieved at 80 °C using as much as 30 mol% of Cu(I)Cl/bpy complex. Similar catalyst loadings were also required for ATRC of dichloroesters to yield medium-sized lactones.^{384,385,420}

8.2.2 Atom Transfer Sequential Radical Addition/Cyclization Processes

The principal advantages of the methodology for catalyst regeneration in atom transfer sequential radical addition/cyclization reactions are twofold. On one hand, the presence of reducing agents enables a significant reduction in the amount of metal catalyst. Such reduction is very beneficial because it increases the radical annulation efficiency by decreasing the rate of radical trapping by the deactivator (transition-metal complex in the higher oxidation state), compared to the rate of radical ring closure. On the other hand, the rate

constant of deactivation can be further controlled through the choice of complexing metal or ligand design.

The results for ATRA followed by sequential ATRC of CCl_4 to various 1,6-dienes (Scheme 20) catalyzed by $[\text{Cu(II)(TPMA)Cl}][\text{Cl}]$ ¹⁸¹ and $\text{Cu(I)Tp}^{\text{X}398}$ ($\text{X} = 3\text{-}t\text{-Bu,5-Me}$ or 3-Cy,4-Br) complexes in the presence of free-radical diazo initiators (AIBN or V-70) and Mg as reducing agents are summarized in Table 5. AIBN or V-70 initiated the ATRA of carbon tetrachloride to 1,6-heptadiene in the absence of a catalyst resulted in approximately 20% yield of the 5-*exo*-trig product, which formed as a result of simple Kharasch addition. For all other dienes investigated, no cyclic products were observed. However, when the $[\text{Cu(II)(TPMA)Cl}][\text{Cl}]$ complex was used in combination with the free-radical diazo initiator, truly remarkable results were obtained. In the presence of AIBN at 60 °C, cyclic products derived from the^{39,40,410,411} addition of CCl_4 to 1,6-heptadiene, diallyl ether

Table 5 ATRA of CCl_4 to 1,6-dienes followed by sequential ATRC catalyzed by copper(I) homoscorpionate ($\text{Cu(I)(Tp}^X\text{)}$) and $[\text{Cu(II)(TPMA)Cl}][\text{Cl}]$ complexes in the presence of free-radical diazo initiators and Mg .^{181,398}

^drt = $22 \pm 2^\circ\text{C}$.

and *N,N*-diallyl-2,2,2-trifluoroacetamide were synthesized in nearly quantitative yields using as low as 0.02 mol% of the catalyst (relative to diene). On the other hand, excellent results with *tert*-butyl-*N,N*-diallylcarbamate and diethyl diallylmalonate were also achieved using even smaller amounts of the catalyst (0.01 mol%). Cyclizations were also very efficient at ambient temperature using V-70 as a reducing agent, although slightly higher catalyst loadings were required (0.04–0.1 mol%). Similarly,

neutral copper(I) homoscorpionate complexes also required higher catalyst loadings at 30°C (1 mol%).³⁹⁸

The data presented in Table 5 also indicate that, regardless of the choice of diene, catalyst, reaction temperature, or reducing agent, 1,2-disubstituted cyclopentanes showed a strong preference for the formation of the cis product, which was also observed in similar free-radical cyclizations that do not utilize transition-metal complexes as halogen atom transfer agents.^{421–423}

Scheme 20 1,6-Dienes used for sequential ATRA followed by ATRC.

Scheme 21 Synthesis of cyclopropanes via sequential ATRA/dechlorination reactions catalyzed by Ru in the presence of Mg.⁴⁰⁵

8.2.3 Sequential Organic Transformations Involving ATRA/ATRC

Apart from being successful for a variety of ATRA/ATRC reactions discussed above,^{39,120,175,177–181,388,395,398,404,405,424,425} the new methodology for catalyst regeneration in the presence of reducing agents was also successfully applied to one-pot synthesis of cyclopropanes via sequential ATRA–dechlorination reactions in the presence of $[\text{Cp}^*\text{Ru(III)Cl}_2(\text{PPh}_3)]$ complex and magnesium.⁴⁰⁵ In this organic transformation, magnesium not only regenerates the active Ru(II) species needed for ATRA and ATRC but also acts as a dechlorination reagent. The reaction sequence is depicted in Scheme 21. Alkenes are first reacted with 1,1'-dichlorides in ruthenium-catalyzed ATRA process. The resulting 1,3-dichlorides are then directly converted into cyclopropanes by reductive coupling with magnesium. Shown in Table 6 are some representative examples for this transformation.

As evident from Table 6, sequential ATRA/dechlorination reactions are applicable to a variety of alkenes (styrene, methyl methacrylate, and cyclohexenylbenzene) as well as alkyl halides (dichloroacetate, chloroform, and dichloroacetonitrile). The corresponding yields of the cyclopropanes are relatively high, with the trans isomer being slightly preferred. Also, the reactions can be conducted in an intramolecular fashion to yield the corresponding

bicyclic cyclopropanes. This has been demonstrated in the case of trichlorinated allylethers and di- and trichlorinated *N*-allylacetamides (Table 6). Cyclopropanes were isolated in yields between 57 and 67% using 1–2 mol% of the $[\text{Cp}^*\text{Ru(III)Cl}_2(\text{PPh}_3)]$ complex in conjunction with 40 equiv of Mg (relative to substrate). It is interesting to note that ATRA/dechlorination of *N*-allyl-2,2-dichloroacetamides yielded the corresponding 3-azabicyclo-[3.1.0]hexan-2-one derivatives, which are precursors of *cis*-2-amino-methylcyclopropanecarboxylic acid (CAMP), a pharmacologically active analog of γ -amino butyric acid (GABA).

Furthermore, in some cases trichloroacetamides yielded a complete dechlorination product in which two 3-azabicyclo-[3.1.0]hexan-2-one fragments were bridged through a carbon–carbon bond. It is quite remarkable that such a complex molecule can be obtained with high diastereoselectivity in a simple one-pot reaction.

Additionally, one-pot sequential reactions involving azide-alkyne $[3 + 2]$ cycloaddition^{426–429} and ATRA catalyzed by $[\text{Cu(II)(TPMA)X}][\text{X}]$ ($\text{X} = \text{Br}^-$ or Cl^- , TPMA = tris(2-pyridylmethyl)amine) in the presence of ascorbic acid as a reducing agent have been reported.⁴³⁰ Reactions with azidopropyl methacrylate and 1-(azidomethyl)-4-vinylbenzene in the presence of a variety of alkynes (phenylacetylene, 3,4-difluorophenylacetylene, propargyl alcohol, 2-methyl-3-butyn-2-ol, methyl propiolate and

Table 6 Sequential ATRA(ATRC)/dechlorination reactions catalyzed by the $[\text{Cp}^*\text{Ru}(\text{III})\text{Cl}_2(\text{PPh}_3)]$ complex in the presence of Mg .⁴⁰⁵

Substrate(s) ^a	Product	t_1 (h)	t_2 (h)	Yield ^b	cis:trans ^c

		1.0 0.50 0.25 0.20	3 3 3 3	~100(89) ^e ~100 85 65

^a All reactions were performed in CH₃OH at 60 °C using [AzPM]₀: [Alkyne]₀ = 1 : 1, [AzPM]₀ = 0.50 M. The amount of ascorbic acid in each system ranged between 20 and 25 equiv relative to copper(II) complex.

^b Mole percent relative to alkyne.

^c Reaction time for azide–alkyne cycloaddition (time for ATRA reaction was 8 h for all substrates with [AzPM]₀: [CCl₄]₀ = 1 : 1.25).

^d The yield is based on the formation of the product and was determined by ¹H NMR spectroscopy using *p*-dimethoxybenzene as internal standard (relative errors are ±15%).

^e Isolated yield for the large scale reaction.

Figure 11 Molecular structure of (*S*)-monoadduct formed by the sequential azide–alkyne [3 + 2] cycloaddition between azidopropyl methacrylate and methyl propiolate followed by ATRA of CBr_4 .

ethyl propiolate), and alkyl halides (carbon tetrachloride, carbon tetrabromide, ethyl trichloroacetate, methyl trichloroacetate, ethyl dichloroacetate, methyl dichloroacetate, dichloroacetonitrile, and 2-bromopropionitrile) proceeded efficiently to yield highly functionalized (poly)halogenated esters and aryls containing triazolyl group in the presence of as low as 0.5 mol% of the catalyst. Some representative examples in the case of CCl_4 are shown in Table 7. The molecular structure of the product isolated from the reaction between azidopropyl methacrylate and methyl propiolate, followed by ATRA of CBr_4 is depicted in Figure 11. It is envisioned that the presented methodology involving a combination of azide–alkyne [3 + 2] cycloaddition and ATRA could have further implications in organic synthesis of functionalized triazoles, which have recently been identified as the lead targets for the screening of potential pharmaceutical drugs.

9 CONCLUSIONS AND FUTURE OUTLOOK

This article focused on TMC ATRP and mechanistically similar ATRA. Both processes utilize TMCs as halogen atom transfer agents. ATRP enables the synthesis of polymeric materials with well-controlled molecular weight, molecular weight distribution, composition, molecular architecture, and chain end functionality. ATRA, on the other hand, is particularly suitable for the synthesis of small and highly functional organic molecules. Basic phenomenology, components (alkyl halide, monomer, solvent and catalyst), as well as current and forthcoming applications are reviewed.

Sb, Bi, Te, and I-Transfer Polymerization and Applications

Shigeru Yamago and Eiichi Kayahara

Institute for Chemical Research, Kyoto University, Uji, Kyoto, Japan

1 INTRODUCTION

Radical polymerization is one of the most successful industrial utilizations of radical chemistry, and nearly 50% of all synthetic polymers are estimated to be produced by this method (see **Radical Polymerization in Industry**). This is primarily because of the robustness of radical polymerization, which originates from the characteristic features of radicals. Owing to soft, neutral, and highly reactive characters of radicals, the polymerization is compatible with a variety of polar functional groups and solvents and usually proceeds under mild conditions.^{1–4} The conditions are strikingly different from other vinyl polymerization methods, namely anion, cation, and coordination polymerizations, which usually require stringent reaction conditions to avoid the occurrence of undesirable side-reactions involving protic solvents, oxygen, and/or polar functional groups. The disadvantage of the conventional radical polymerization is, however, insufficient control of the macromolecular structure of the resulting polymers and gives macromolecules that are polydisperse with a broad molecular weight distribution (MWD). While living anionic^{5,6} cationic,^{7,8} and coordination polymerization^{9–11} have already been developed to control molecular weights, MWDs, and monomer sequences through block copolymer synthesis, the living version of radical polymerization has become possible only recently.

The living or controlled radical polymerization (LRP) has been becoming an indispensable method for creating well-controlled but highly complex macromolecules with the hope that they will lay the essential foundation for new polymeric materials with improved and/or new properties and functions.

The difference between LRP and conventional radical polymerization is that the activity of polymer-end species is preserved throughout the polymerization period by reversible generation of the radical from a so-called dormant species, which possesses appropriate functional groups at the polymer end for radical generation (Scheme 1).^{12,13} This “pseudo” deactivation of the polymer-end radical to the dormant species decreases the concentration of radical species in solution and minimizes undesirable side reactions leading to dead polymers. Furthermore, the rapid deactivation makes it possible to elongate all the polymer chains with similar chain lengths. The faster deactivation leads to higher control of MWD under an ideal condition without any termination reactions.

LRPs that have been widely used include nitroxide-mediated radical polymerization (NMP, see **Nitroxide-Mediated Polymerization and its Applications**),¹⁴ atom-transfer radical polymerization (ATRP, see **Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**),^{13,15–17} and reversible addition–fragmentation chain-transfer

Scheme 1 General mechanism of LRP. P and X denote polymer-end and capping species, respectively.

radical polymerization (RAFT, see **Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications**).^{18–20} Organostibine-,^{21–24} organobismuthine-,^{25,26} and organotellurium-mediated^{27–34} LRP (SBRP, BIRP, and TERP, respectively)^{35,36} are relatively new methods developed by the author's research group. New variants of LRP have also emerged, such as cobalt-mediated polymerization,³⁷ single-electron transfer LRP,^{38–40} and titanium-catalyzed polymerization.⁴¹ Organoiodine-mediated LRP (IRP), which is one of the oldest LRP,⁴² has also been used in many instances. Each method utilizes unique chemical structures and activation/deactivation mechanisms of the dormant species, and these differences make each LRP method unique both mechanistically and synthetically.

This review surveys the synthetic and mechanistic aspects of SBRP, BIRP, TERP, and IRP, all of which proceed through similar activation/deactivation mechanism of dormant and radical species. One of the theoretical criteria of the livingness in LRP is low MWD ($M_w/M_n < 1.5$, where M_w and M_n refer to weight and number average molecular weights, respectively), which is inaccessible by the conventional radical polymerization (see **Fundamentals of Controlled/Living Radical Polymerization**). Therefore, examples that meet the criteria are only included in this review. In addition, while organoiodine compounds are sometimes used as initiators for ATRP in the presence of a metal catalyst, such examples are also excluded in this article. Recent developments in LRP under different methods (see **Nitroxide-Mediated Polymerization and its Applications, Reversible Addition Fragmentation Chain Transfer (RAFT) Polymerization: Mechanism, Process and Applications and Atom Transfer Radical Polymerization (ATRP) and Addition (ATRA) and Applications**) and background and kinetics of the LRP (see **Fundamentals of Controlled/Living Radical**

Polymerization and Kinetics of Polymerizations) are also included in this article.

2 BACKGROUND: EARLY DEVELOPMENTS IN ORGANOHETEROATOM-MEDIATED LRP

Radical-mediated atom-transfer addition reactions of haloalkanes to alkenes in the presence of a radical initiator were first reported by Kharasch in 1945 (Scheme 2a).^{43,44} This type of reaction has caught attentions from organic chemists since the rediscovery of the iodine group transfer radical addition reaction by Curran in 1986.^{45–47} Phenylselenyl group transfer and phenyltellanyl group transfer radical addition reactions of organoselenides and organotellurides, respectively, were subsequently reported by several groups.^{48–57} The reaction proceeds by a radical chain reaction, and carbon-centered radical R generated from an organoheteroatom compound, R–X, reacts with an alkene or alkyne to generate a new carbon-centered radical (1), which reacts with R–X to give the addition product with the regeneration of R radical (Scheme 2b).

Repetition of atom or group transfer addition reactions to alkenes leads to the formation of living polymers possessing heteroatom functionality X at the ω -polymer end (Scheme 2a). The effect of heteroatom compounds on the control of MWD was recognized for the first time by Tatemoto and coworkers, who observed the living character of radical polymerization of fluorinated monomers by the addition of organoiodine compounds, $(CF_3)_2CFI$, and obtained polymers with low MWDs.⁵⁸ They also observed the linear increase in the molecular weight versus the conversion and also successfully synthesized block copolymers. The drawback of IRP is, however, its low versatility, and other conventional monomers, such as styrene and (meth)acrylate derivatives, have been used with only limited success.^{59–66} Several new conditions have been recently reported to increase the control in IRP. For example, Kamigaito and coworkers reported that fluoroalcohols are effective solvents to increase the control of tacticity and MWDs in the polymerization of vinyl acetate.⁶⁷ They also found that manganese-mediated photo-induced polymerization considerably increased the polymerization of conventional monomers.^{68–70} Goto and coworkers

Scheme 2 (a) Atom and group transfer radical addition reaction and (b) its mechanism.

have recently developed a modified version of IRP, in which several inorganic and organic halides, phenols, and hydrocarbons in the presence of conventional organoiodine chain-transfer agents (CTAs) increase the control of MWD in IRP.^{71–76} They call this method as *reversible chain transfer-catalyzed polymerization* (RTCP), because inorganic or organic radicals generated from the additives reversibly activate organoiodine CTAs. Since various monomers gave structurally well-controlled polymers with MWD of below the theoretical limit by RTCP, synthetic and mechanistic aspects of these results are discussed in this article.

Kwon *et al.*^{77–79} have utilized diaryldiselenides as a photoiniferter or radical trapping agent,⁸⁰ which generate organoselenium dormant species *in situ* by the reaction of the monomers. They also employed phenylselenenyl-substituted CTAs for the polymerization of styrene (St) under photo irradiation.⁸¹ The polymerization showed living character as judged from a linear increase in M_n on monomer conversion and successful synthesis of block copolymers. However, the control of MWD was insufficient, and polymers with considerably high MWDs were obtained ($M_w/M_n > 1.5$). The same group also reported the effect of diphenylditelluride on the conventional 2,2-azobisisobutyronitrile (AIBN)-initiated radical polymerization of St.⁸²

They found that MWD becomes narrow ($M_w/M_n = 1.26–1.18$) with the addition of more than 0.5–2.0 equiv of diphenylditelluride to AIBN, whereas the addition of more ditelluride led to the formation of polystyrene (PS) with lower M_n . They also propose the existence of a phenyltellanyl-substituted ω -polymer-end group, but there was no direct evidence to support the end group structure.

On the basis of the findings of reversible radical generation from organotellurium compounds via carbon–tellurium bond thermolysis and photolysis^{83,84} and its applications to organic synthesis,^{85–92} Yamago and coworkers developed TERP, SBRP, and BIRP.^{35,36,93} The details of these methods are discussed below.

3 ORGANOHETEROATOM-MEDIATED LRP

3.1 Chain Transfer Agents

CTAs applied to the controlled polymerization under SBRP, BIRP, TERP, and IRP are summarized in Scheme 3. Although organostibine, organobismuthine, and organotellurium CTAs are moderately air (oxygen) sensitive, they can be stored for long periods under a nitrogen atmosphere and are handled using standard syringe techniques. Organoiodine

Scheme 3 Structures of organoheteroatom CTAs.

Scheme 4 Synthetic route to organoheteroatom CTAs.

CTAs are stable to air, but they easily decompose by heat and light with elimination of HI. Therefore, organoiodine CTAs cannot be stored for a long period. This is probably because C–I bond is more ionic than C–Sb, C–Bi, and C–Te bonds.

The availability of CTAs is a key issue with respect to practical applications of LRPs. Many of the organoheteroatom CTAs shown in Scheme 3 are prepared on large scales and easily purified. Most scalable synthetic route to these CTAs are ionic reaction, such as an enolate route for the preparation of organostibine and bismuthine CTAs (Scheme 4a) and halogen (usually bromine)-heteroatom exchange reaction for organotellurium and organoiodine CTAs (Scheme 4b). Radical chemistry also plays important role in the preparation of CTAs, especially those possessing polar functional groups.

As the heteroatom functional groups in the CTAs are moderately sensitive to oxygen and also reactive under various conditions, postmodifications to introduce functional groups starting from the existing CTAs are limited. In addition, as the synthesis of CTAs requires basic conditions, many polar functional groups are not compatible. The method shown in Scheme 4c, which relies on the reaction of a radical generated from an azo-initiator with distibines,²³ ditellurides,³⁰ and molecular iodine^{61,62,65,66,72,74} proceeds under neutral conditions and is applicable to the synthesis of functional CTAs.

The reaction of azo-initiators with tetramethyl-distibine and molecular iodine took place with high coupling efficiencies. Yields of the CTAs were about 60% when a 1:1 mixture of an azo-initiator and the distibine molecular iodine was employed. Since about 40% of the radicals generated from the azo-initiators dimerize within a solvent cage,⁹⁴ the result indicates that almost all the radicals

that diffused from the cage were captured by the distibine and iodine. Organostibine CTAs **Sb-3**, **Sb-6**, **Sb-7**, **Sb-8**, and **Sb-9** were prepared via this route starting from the corresponding azo-initiators. Ester, ether, terminal alkene, and alcohol groups were incorporated into the CTAs. α -Functional polymers were synthesized starting from these functional CTAs (see below). On the contrary, trapping of radicals by ditellurides was insufficient and gave the desired CTAs in low yields (8–18%).

Goto and Tsujii recently reported that benzyl alcohol and its derivatives can be used as an initiator for the polymerization of methyl methacrylate (MMA) in the presence of *N*-iodosuccinimide (NIS) and AIBN under RTCP conditions.⁷⁵ Hydroxyl radical generated from an alcohol and NIS reacts with a monomer followed by trapping with iodine source generating an organoiodine dormant species. Among primary, secondary, and tertiary alcohols, the primary alcohol exhibited the highest initiation efficiency, but the efficiency was at most 55%.

3.2 Additives (Cocatalysts)

Several diheteroatom compounds, such as tetra-methyl distibine, tetraphenyl distibine, 2,6-dimesitylphenylthiodiphenylbismuthine (**Bi-S**), dimethyl ditelluride, dibutyl ditelluride, and diphenyl ditelluride, were used as an additive to SBRP, BIRP, and TERP (Scheme 5a). These compounds considerably increase the MWD control by affecting the activation/deactivation reactions of the dormant/radical species (see mechanistic section in detail). However, they do not directly generate initiating radicals and, thus, new polymer chains. Therefore, these compounds can be regarded as a

cocatalyst in controlling the MWD. A binary system consisting of an organoheteroatom CTA and a cocatalyst and a ternary system consisting of a CTA, a cocatalyst, and a conventional radical initiator were employed for the LRP (see Section 3.4).

Vast array of compounds having X–I and X–H bonds, in which X refers to carbon and heteroatom, are reported to be effective cocatalysts to increase the MWD control in the presence of organoiodine CTAs under RTCP condition (Scheme 5b). These compounds include inorganic and organic heteroatom compounds, such as SnI_4 , GeI_4 , *p*-tolyl- GeI_3 (TolGeI₃), PI_3 , butyl phosphite, ethyl phenylphosphinate, ethyl phosphite, NIS, succinimide, and maleimide, phenol derivatives, such as thymol diiodide, phenol, 2,4-dimethylphenol (2,4-Me), thymol, 2,4,6-trimethylphenol, dibutylhydroxytoluene, dibutylhydroxyanisole, vitamin E, 4-cyano-2,6-dimethylphenol (2,6-Me-4-CN), catechol, resorcinol, hydroquinone, 4-*t*-butyl catechol, hydroxyl hydroquinone (HHQ), morin hydrate (MH), uric acid (UA), and vitamin C, and carbon compounds, such as Cl_4 , 1,4-cyclohexadiene, diphenylmethane, fluorene, xanthene (XT), and thioxanthene (TXT). Synthetic scope and the role of the diheteroatom compounds are discussed in the following section.

3.3 Structural Effect of CTAs on the Control of LRP

Besides the requirement of the efficient activation/deactivation reaction in LRP for the control of MWD, the general requirement for the control of MWD in living polymerization is the efficient initiation reaction. This step must be faster than or at least similar to the propagation step. To ensure the fast activation reaction, CTAs mimicking the polymer-end structure have been used for all methods.

Structures of organoheteroatom CTAs on the control of MWDs are generalized in Scheme 6. Specific examples using organotellurium CTAs are summarized in Table 1. These CTAs mimic the polymer-end structure of polymethacrylate, polymethacrylonitrile, polyacrylate, and PS. Ester and nitrile groups stabilize carbon-centered radicals about 40 kJ mol^{-1} and phenyl group about 70 kJ mol^{-1} by conjugation when hydrogen is replaced by these groups.⁹⁵ Alkyl group also stabilizes its α -radical via hyperconjugation by about $15\text{--}20 \text{ kJ mol}^{-1}$. Therefore, the radical species generated from **2**, **3**, and **4** are about 20 kJ mol^{-1} more stable than those from **5** and **6**, as indicated by the bond dissociation energies (BDEs) of methyltellanyl derivatives ($\text{X} = \text{TeMe}$, Table 1). In addition, the reactivities of the radicals generated from these CTAs to monomers are similar when the radical possesses same stabilizing group. Therefore, CTAs having polymethacrylate and polymethacrylonitrile structures show higher control than polyacrylate structures, and phenylethyl-substituted CTAs mimicking PS polymer end are better CTAs than benzyl derivatives. The same structural effects on the control of MWD have also been observed in NMP,^{96,97} ATRP,⁹⁸ and RAFT.⁹⁹ It should be noted that control of the MWD does not always correlate to the BDEs of CTAs as well as those of dormant species because bond homolysis is not the main mechanism of the activation of dormant species in SBRP, BIRP, TERP, and IRP as discussed in the mechanistic section.

3.4 Polymerization Conditions

Three conditions have been developed for conducting SBRP, BIRP, TERP, and IRP. These conditions are defined by the method for generating initiating radical species as discussed in the mechanistic section. The first condition (A in Table 2) is a purely thermal condition, in which a CTA and

Scheme 6 Structural effect of CTA on the control of LRP.

Table 1 Structural effect of organostibine,²¹ organobismuthine,²⁵ and organotellurium^{27,29,33} chain-transfer agents (CTAs) on the polymerization of styrene (100 equiv) under thermal conditions.

^aConditions: (A) A mixture of chain-transfer agent (**Te-1**) and monomer (1 : 100) was heated.²⁷ (B) A mixture of AIBN, chain-transfer agent (**Te-1** or **Te-7**), and monomer in a ratio of 1 : 1 : 100 was heated.²⁹ (C) A mixture of chain-transfer agent (**Te-3**) and monomer was irradiated with a 500-W high-pressure Hg lamp through a cutoff filter.³⁴^b2,2'-Azobis(4-methoxyvaleronitrile) was used instead of AIBN.^cOne equiv of dimethyl ditelluride was added.

a monomer are typically heated between 80 and 110 °C.^{27,28} BIRP and TERP proceed under this condition. The second condition (B) is a ternary system consisting of a radical initiator, a CTA, and a monomer,²⁹ and all methods proceed under this condition. Azo-initiators are typically employed under thermal conditions, but photo-initiators are also utilized. The polymerization conditions depend on the decomposition temperature of the initiator used, and it usually proceeds at lower temperature than that of the condition A. The third condition (C) proceeds under photo irradiation of a mixture of an organotellurium CTA and a monomer,³⁴ and the

polymerization proceeds under much milder conditions, such as temperatures in the range of 0 °C to room temperature. The cocatalysts can be added to the above-mentioned conditions to improve the MWD control.

Effects of the conditions on the polymerization of *n*-butyl acrylate (BA), St, and MMA in the presence of organotellurium CTAs **Te-1**, **Te-3**, and **Te-7** are summarized in Table 2. Polymerization of BA (100 equiv) under the condition A was sluggish and monomer conversion reached 70% after being heated at 100 °C at 24 hours. Despite long reaction time required to achieve high monomer

conversion, poly(butyl acrylate) (PBA) with narrow MWD ($M_w/M_n = 1.12$) was obtained. Polymerization under the condition B, on the other hand, completed within 0.5 hours at 60 °C by the addition of AIBN and gave well-controlled polymers ($M_w/M_n = 1.17$). Uncontrolled free radical polymerization did not compete with LRP even in the presence of azo-initiators. Polymerization proceeded even at 0 °C under condition C, and PBA with a narrow MWD ($M_w/M_n = 1.16$) was also obtained with high monomer conversion.

Polymerization of St and MMA under the conditions A and B has been reported. Polymerization of St and MMA under condition A proceeded in the temperature range of 80–100 °C and that under condition B with AIBN as an initiator proceeded at 60 °C. Polymerization of St using condition B took place at 40 °C with 2,2'-azobis(4-methoxyvaleronitrile) as an initiator, which decomposes at a lower temperature than AIBN does. High level of control of MWD ($M_w/M_n = 1.12$ – 1.21) was observed regardless of the method used.

Since polymerization takes place at lower temperatures and with shorter reaction times under conditions B and C than those under condition A, these methods should be suitable for monomers that undergo unwanted side reactions at high temperatures. The high energy efficiencies of conditions B and C are also useful for industrial applications.

Since thermolysis of the dormant species is the rate determining step in condition A (see mechanistic section in detail), the rate of polymerization is strongly affected by the strength of the carbon–heteroatom bond of the dormant species. The PBA dormant species has a higher BDE than the PS- and poly(methyl methacrylate) (PMMA) dormant species do by an analogy from the BDEs of structurally related CTAs (Table 1). Therefore, the polymerization of BA required a higher temperature and a longer reaction time than those of St and MMA. Conversely, the rate control step is usually the propagation reaction in condition B because the initiating radicals are provided from azo-initiators. Therefore, the rate of polymerization is similar to the propagation rate; BA is the fastest followed by MMA and then St.

SBRP, BIRP, TERP, and IRP are routinely carried out without solvent (bulk polymerization), but several solvents have also been used. Polar solvents, such as *N,N*-dimethylformamide (DMF)

and tetrahydrofuran, were used for the polymerization of *N*-isopropylacrylamide (NIPAM), acrylonitrile (AN), *N*-vinylcarbazole (NVC), and acrylic acid (AA).^{21,25,28,34} TERP of NIPAM was also carried out in a DMF/water mixture at 20 °C under condition C.³⁴ RTCP of polar monomers, such as glycidyl methacrylate (GMA), hydroxyethyl methacrylate (HEMA), phenyl methacrylate (PHMA), and AN were carried out in anisole, ethanol, 1-propanol, methyl ethyl ketone, ethylene carbonate, and dipropylene glycol monomethyl ether.^{71,73,76}

Owing to the high compatibility of water, TERP³¹ and RTCP¹⁰⁰ were applied to a mini-emulsion condition by Okubo *et al.* also reported that TERP of BA and St could be carried out under emulsifier-free emulsion polymerization conditions by employing a water soluble macro-CTA, PMMA₃₀-TeMe, and a water soluble azo-initiator.^{101–103} These results demonstrate the applicability of TERP and RTCP in aqueous heterogeneous systems.

3.5 Synthetic Scope: Homopolymerization

A synthetic advantage of SBRP, BIRP, TERP, and IRP (RTCP) is their high versatility in polymerizing a variety of monomer families using the same CTAs. Selected monomers polymerized in a controlled manner using these methods are summarized in Scheme 7. M_n and MWD data were taken from the polymerization using CTAs with general structures **2**, **3**, and **4**. The monomer conversions are usually high (>90%), and polymers with narrow MWDs were obtained in all cases.

3.5.1 Styrenes

St was polymerized under conditions A and B by SBRP, BIRP, and TERP with and without a cocatalyst, and structurally well-defined PS with M_n close to the theoretical values and low MWDs was formed.^{25,27,29,30,33} M_n increased linearly with an increase in the St/CTA ratio, and PSs with M_n in the range of 3000–87 000 and narrow MWDs ($M_w/M_n < 1.3$) were prepared in the absence of a cocatalyst. *p*-Chlorostyrene (*p*ClSt) and *p*-methoxystyrene (*p*MeOSt) were also successfully polymerized.²⁷ Although the MWD control in

Unconjugated monomers

Scheme 7 Selected monomers polymerized using (a) SBRP, (b) BIRP, (c) TERP, and (d) IRP (RTCP). Polymerization data (M_n and M_w/M_n values) were taken from the data obtained using CTAs having general structures **2**, **3**, and **4** (M_n was given in g mol^{-1}).

*p*ClSt polymerization was less efficient than those in St and *p*MeOSt polymerizations, presumably due to the higher propagation rate of the former than the latter, the level of control was still below the theoretical limit.

A binary system consisting of a distibine and organostibine CTA^{23,104} and a ditelluride and

organotellurium CTA¹⁰⁵ was effective to increase the MWD control of St polymerization, but the effect was less pronounced than that in methacrylate polymerization as discussed below. Both low and high molecular weight PSs with M_n s in the range of $1.0 \times 10^4\text{--}2.0 \times 10^5 \text{ g mol}^{-1}$ and narrow MWDs ($M_w/M_n = 1.07\text{--}1.15$) were synthesized with high

monomer conversion (>90%) by adding a catalytic amount of thiobismuthine cocatalyst **Bi-S** to organobismuthine CTA **Bi-1**.²⁶

IRP of St was less successful than SBRP, BIRP, and TERP, and PS with considerable broad MWD was obtained even when the targeted molecular weight was low ($M_n \sim 6500 \text{ g mol}^{-1}$, $M_w/M_n \sim 1.4$) using **I-1** as a CTA.⁶⁰ This is primarily due to the low exchange constant C_{ex} in IRC than that in other methods as discussed in the mechanistic section. Polymerization under RTCP conditions, on the other hand, significantly increases the MWD control.^{71–73, 76} Polymerization of St in the presence of an organoiodine CTA and a cocatalyst listed in Scheme 5b gave PS with narrow MWDs ($M_n = 2500\text{--}27\,000 \text{ g mol}^{-1}$, $M_w/M_n = 1.16\text{--}1.48$). Phenol derivatives were especially effective among the cocatalysts, and PSs with $M_n \sim 7000 \text{ g mol}^{-1}$ and $M_w/M_n < 1.2$ were obtained by the addition of 2,4,6-Me, vitamin E, HHQ, UA, and MH.⁷⁶

3.5.2 Methacrylates

SBRP and BIRP exhibited higher MWD control than TERP in methacrylate polymerization, and PMMAs with narrow MWDs ($M_w/M_n = 1.10\text{--}1.25$) and M_n in the range of $10\,000\text{--}100\,000 \text{ g mol}^{-1}$ were obtained. The MWD control further increased on addition of distibine cocatalysts in SBRP. For example, SBRP of MMA using **Sb-1** proceeded with reasonable MDW control ($M_w/M_n = 1.24$) and that in the presence of 0.1 equiv of tetramethyldistibine afforded PMMA with highly controlled structures ($M_w/M_n = 1.05$).²³ The addition of further distibine, on the other hand, had virtually no effect on the MWD control, and significant rate retardation of the polymerization was observed. PMMAs of higher molecular weights ($M_n = 34\,700\text{--}122\,900 \text{ g mol}^{-1}$) and very narrow MWDs ($M_w/M_n = 1.05\text{--}1.15$) were prepared by increasing the ratio of MMA to **Sb-1** in the presence of 0.1 equiv of tetramethyldistibine. Methacrylonitrile was also polymerized in a controlled manner by BIRP.¹⁰⁶

The control of MWD in the polymerization of methacrylate was not always sufficient via TERP. Polymerization of MMA using organotellurium CTAs resulted in the formation of PMMAs with

considerably broad MWDs ($M_w/M_n > 1.37$). However, the control increased with the addition of ditellurides as a cocatalyst, such as dimethyl, dibutyl, and diphenylditelluride, and PMMAs with narrow MWDs ($M_w/M_n = 1.12\text{--}1.16$) and M_n in the range of $8600\text{--}79\,400 \text{ g mol}^{-1}$ were obtained depending on the monomer/CTA ratio.^{28,30} A catalytic amount of ditelluride was effective when the targeted molecular weight was small, but substoichiometric to excess amounts of ditelluride were used when the targeted molecular weight was large.

IRC of MMA afforded PMMAs with broad MWDs ($M_w/M_n > 1.5$),^{60,62} but RTCP of MMA gave PMMAs with narrow MWDs ($M_n = 6300\text{--}13\,000 \text{ g mol}^{-1}$, $M_w/M_n = 1.22\text{--}1.38$).^{71,73,76} Among the cocatalysts, Tol-GeI₃, XT, and TXT exhibited superior cocatalyst for the increased control. Ethylhexyl methacrylate, benzyl methacrylate (BzMA), and PHMA with $M_n \sim 10\,000 \text{ g mol}^{-1}$ were also polymerized in a controlled manner under RTCP conditions ($M_w/M_n = 1.16\text{--}1.33$).

3.5.3 Acrylates

Acrylates, acrylamides, and AN were polymerized in a controlled manner under conditions A, B, and C by SBRP, BIRP, and TERP. However, IRC of acrylates resulted in low control with broad MWDs ($M_w/M_n > 1.6$).^{60,61} Polymerization of acrylates under RTCP condition has not been reported so far.

High temperature and long reaction times were required to reach high monomer conversion under condition A due to inefficient generation of the initiating radicals from the dormant species.²⁸ The high temperatures were also unsuitable because a considerable amount of branching occurred due to a back-biting reaction.^{107–109} Therefore, conditions B²⁴ and C³⁴ at low to ambient temperature are more suitable for the polymerization of these monomers. PBAs with narrow MWDs ($M_w/M_n = 1.10\text{--}1.20$) and M_n in the range of $11\,000\text{--}122\,000 \text{ g mol}^{-1}$ were successfully synthesized at 60°C using BIRP under condition B with AIBN as the initiator. Polymerization of BA proceeded in the temperature range of $0\text{--}50^\circ\text{C}$ using TERP under UV-vis irradiation (condition C), and PBAs with narrow MWDs ($M_w/M_n = 1.08\text{--}1.19$) and M_n in the range of $13\,000\text{--}223\,000 \text{ g mol}^{-1}$ were synthesized.

Addition of thiobismuthine cocatalyst **Bi-S** was especially suitable for the synthesis of ultrahigh molecular weight polyacrylates. PBAs with M_n s in the range of 1.2×10^4 – 2.8×10^6 g mol⁻¹ and narrow MWDs ($M_w/M_n = 1.06$ – 1.43) were prepared under mild thermal conditions under a ternary system consisting of **Bi-1**, **Bi-S**, and AIBN. The Gel Permeation Chromatography (GPC) traces of all of the PBAs were unimodal, and the peak maxima shifted to higher molecular weights as the targeted molecular weight increased (Figure 1). A PBA with an M_n of 1.4×10^6 g mol⁻¹ and a narrow MWD ($M_w/M_n = 1.22$) was obtained at 47% monomer

conversion when 20 000 equiv of BA was employed. Moreover, a PBA with an M_n of 2.8×10^6 g mol⁻¹ was obtained at 41% monomer conversion when 50 000 equiv of BA was employed. Although the MWD was slightly large ($M_w/M_n = 1.43$), it is still below the theoretical limit.

A significant drawback of LRP is the synthesis of high molecular weight polymers because the polymer-end radicals are always subject to irreversible termination reactions.¹¹⁰ Only a few examples have been reported for the synthesis of ultrahigh molecular weight polyacrylates and polymethacrylates with M_n s exceeding

Figure 1 GPC traces of PBA samples prepared by varying the BA/**Bi-1** ratio in the presence of **Bi-S** measured by GPC columns with exclusion limits of (a) 2×10^6 and (b) 2×10^7 (M_n was given in g mol⁻¹). [Reprinted from Ref. 26. © American Chemical Society, 2009.]

$1 \times 10^6 \text{ g mol}^{-1}$ and with narrow MWDs: RAFT¹¹¹ and ATRP^{112,113} under high pressure conditions, Single-electron transfer LRP using a copper catalyst,¹¹⁴ and ATRP under mini-emulsion conditions.¹¹⁵ Therefore, BIRP in the presence of **Bi-S** provides a new route to structurally well-defined ultrahigh molecular weight polymers.

3.5.4 Functional Monomers

Since SBRP, BIRP, TERP, and IRC (RTCP) are performed under thermal or photochemical conditions without catalysts that are incompatible with the functionalities of the monomers, controlled polymerization of various monomers possessing functional groups was achieved.^{28,34,71–73,76} For example, methacrylates and acrylates with a free hydroxyl group, such as HEMA and hydroxyethyl acrylate, a carboxylic acid group, such as AA, and an amine group, such as *p*-aminostyrene, *N,N*-dimethylaminoethyl methacrylate (DMAEMA), *N,N*-dimethylaminoethyl acrylate, were polymerized using TERP and RTCP in a controlled manner. Acryl amides, such as *N,N*-dimethylacrylamide and NIPAM also gave the corresponding controlled polymers by SBRP, BIRP, and TERP. Monomers possessing epoxide and ethers, such as GMA and poly(ethylene glycol)methacrylate (PEGMA), were also polymerized under RTCP conditions. Protection of the acidic proton in the hydroxyl, carboxylic acid, and amide groups was not necessary because polymerization proceeded under neutral conditions and carbon–heteroatom bonds in the dormant species are resistant to polar functional groups.

3.5.5 Unconjugated Monomers

The most notable feature of these LRP methods is that they can control the polymerization of both conjugated and unconjugated monomers using the same CTAs.^{21,25,32,34} Since polymer-end radicals generated from unconjugated monomers are less stable than those from conjugated monomers, the dormant species of unconjugated monomers possess stronger carbon–heteroatom bond than those of conjugated monomers. Therefore, conditions B and C are effective for the polymerization of unconjugated monomers.

Scheme 8 Structure of head-to-tail (H-T) and head-to-head (H-H) addition adducts at ω -polymer-end group in PVAc.

SBRP, BIRP, and TERP of *N*-vinylpyrrolidone (NVP) afforded poly(*N*-vinylpyrrolidone)s (PNVPs) with M_n in the range of 3100–83 500 g mol^{-1} and narrow MWDs ($M_w/M_n = 1.06–1.29$). *N*-Vinylimidazole and NVC were also polymerized in a controlled manner using TERP under photo irradiation.^{21,22,25,32,34}

Polymerization of vinyl acetate (VAc) using SBRP²¹ and TERP¹¹⁶ gave the controlled poly(vinyl acetate)s (PVAc)s, but the control was limited to low molecular weight polymers ($M_n < 5000 \text{ g mol}^{-1}$) due to the formation of dormant species by head-to-head (H–H) addition reaction.¹¹⁶ IRC showed better control than TERP and SBRP, and PVAc of M_n ranging from 4000 to 34 000 g mol^{-1} were synthesized under controlled manner ($M_w/M_n < 1.5$).¹¹⁷ Kamigaito and coworkers have recently shown that PVAc with considerable high molecular weights were synthesized with narrow MWD ($M_n \sim 45\,000 \text{ g mol}^{-1}$, $M_w/M_n < 1.5$) by IRP carrying out the polymerization in a fluoroalcohol solvent.⁶⁷ While fluoroalcohols were used to control the tacticity by coordination to VAc, its effect on the tacticity was marginal. Instead, the solvents perturb the monomer reactivity and decrease the formation of the H–H adduct (Scheme 8). Since the H–H adduct serves as a dead polymer, its reduction leads to the increased control of VAc polymerization (see Section 4.1).

3.6 Random and Alternating Copolymerization

Copolymerization, in which a mixture of two or more monomers is polymerized, is a powerful synthetic technique to modulate the properties of polymer materials. Therefore, the controlled copolymerization would provide a diverse range of polymeric materials. Goto and coworkers reported random copolymerization of methacrylate derivatives under RTCP conditions (Scheme 9). A

Scheme 9 Combination of methacrylate monomers used for copolymerization under RTCP condition (M_n was given in g mol^{-1}).

various combination of methacrylate derivatives, such as MMA and BzMA, MMA and HEMA, BzMA and HEMA, BzMA and DMAEMA, and MMA and methacrylic acid (MAA), with M_n ranging from 5400 to 19 000 g mol^{-1} , gave the desired copolymer with controlled structure ($M_w/M_n < 1.5$). While there are no reports on random copolymerization of conjugated monomers by SBRP, BIRP, and TERP, it is reasonable to assume that the copolymerization will proceed in a controlled manner.

Mishima and Yamago¹¹⁸ reported that copolymerization of (meth)acrylate monomers, conjugated monomers, and vinyl ethers, unconjugated monomers, took place with high MWD control. Furthermore, high alternating monomer sequence was achieved by employing an excess amount of vinyl ethers (5–10 times) over methacrylates (Scheme 10a). For example, when a 1:1 mixture of 2,2,2-trifluoroethyl acrylate (TFFA) and isobutyl vinyl ether (IBVE) was polymerized in the presence of organotellurium CTA **Te-1**, the resulting

Scheme 10 (a) Controlled alternating copolymerization of (meth)acrylates and vinyl ethers and (b) combination of (meth)acrylate/vinyl ether monomers in random and alternating copolymerization by TERP, SBRP, and BIRP (M_n was given in g mol^{-1}).

copolymer possessed low MWD ($M_w/M_n = 1.12$) with mole fraction of IBVE ($MF_{IBVE} = 0.43$). The polymerization did not proceed further after all the TFEA was consumed, and IBVE remained under the polymerization conditions. This is because vinyl ethers do not homopolymerize under radical conditions. A polymer-end radical formed from TFEA reacts with TFEA and IBVE, but that formed from IBVE only reacts with TFEA. Therefore, more TFEA than IBVE was incorporated.

When the amount of IBVE was increased (IBVE/TFEA = 5), nearly complete alternating copolymer with $MF_{IBVE} = 0.49$ and controlled MWD ($M_w/M_n = 1.18$) was formed. The alternating structure was confirmed by two-dimensional NMR and mass spectroscopy analyses. This alternating copolymerization took place for the combination of various (meth)acrylates and vinyl ethers: TFEA and *t*-butyl vinyl ether (*t*BVE), TFEA and trimethyl(vinyloxy)silane (TMVS), BA and IBVE, BA and TMSV, *t*BA and *t*BVE, MMA and IBVE, and MMA and IBVE (Scheme 10b). Highly controlled alternating copolymers with respect to MWD and monomer sequence were formed in all cases under TERP, SBRP, and BIRP conditions.

3.7 Block Copolymerization

Block copolymers comprise two or more homopolymer subunits linked by covalent bond and are regarded as next-generation functional materials for a variety of applications, such as photonic, magnetic, and electronic materials, thermoplastic elastomers, adhesives, and dispersants. In addition, the morphology of the phase separated structure of block copolymers have been utilized for fabrication of structurally well-controlled nano-structure based on the bottom-up approach.^{119–121} Therefore, the controlled synthesis of new block copolymer represents a challenge in nano-sciences and technologies.

A notable feature of SBRP, BIRP, and TERP is their versatility in the synthesis of block copolymers. Although the success of block copolymer synthesis is, in general, highly dependent on the order of monomer addition, especially when different families of monomers are used, these methods are more tolerant toward the order of addition than other LRP methods.^{122–125} For example, blocking of the PS macro-CTA was successfully carried out

for MMA and *t*BA, and the desired AB-diblock copolymers with narrow MWDs were obtained in both cases (Scheme 11).²⁸ The essentially complete disappearance of the starting macro-CTAs and the formation of the desired diblock copolymers were observed. The addition of ditelluride is necessary when MMA is used as a monomer. The controlled syntheses of AB-diblock copolymers starting from a PMMA macro-CTA with St and *t*BA, or from a poly(*t*-butyl acrylate) (*Pt*BA) macro-CTA with St and MMA, were also examined. Desired diblock copolymers with narrow MWDs ($M_w/M_n < 1.35$) were synthesized in all cases regardless of the order of monomer addition.

As the order of monomer addition is less important in TERP compared to that in other LRP methods, it was possible to prepare ABA and ABC triblock copolymers starting from diblock macro-CTAs (Scheme 11). Treatment of PMMA-*block*-PS and PMMA-*block*-*Pt*BA macro-CTAs with MMA gave the desired ABA triblock copolymers with narrow MWDs. ABC-triblock copolymers with different monomer sequences of St, MMA, and *t*BA, namely PS-*block*-PMMA-*block*-*Pt*BA, PMMA-*block*-PS-*block*-*Pt*BA, and PMMA-*block*-*Pt*BA-*block*-PS, were also synthesized in a controlled manner by the sequential addition of each monomer.

Block copolymers comprising conjugated and unconjugated monomers were also synthesized in a controlled manner using SBRP, BIRP, and TERP.^{21,22,25,32} Synthesis of these block copolymers is more difficult than that from both conjugated monomers because stabilities and reactivities of the dormant species and polymer-end radicals derived from conjugated and unconjugated monomers are quite different. Polymerization of organostibine and organobismuthine PS macro-CTAs with NVP in the presence of AIBN in DMF at 60 °C resulted in the complete consumption of the CTAs and the formation of desired PS-*block*-PNVP in high monomer conversion (Scheme 12). The diblock copolymers composed of different compositions of PS and PNVP segments were successfully synthesized in a controlled manner ($M_w/M_n = 1.05–1.28$) by altering the molecular weight of PS macro-CTAs and the amount of NVP. PMMA-*block*-PNVP was also synthesized in a controlled manner ($M_n = 20500 \text{ g mol}^{-1}$, $M_w/M_n = 1.31$) by treating an organostibine-PMMA macro-CTA with NVP in the presence of AIBN. Although the block polymer synthesis starting from PNVP macro-CTA

*[MeTe]₂ [1 equiv] was added.

Scheme 11 Syntheses of AB-block, ABA-triblock, and ABC-triblock copolymers using St, MMA, and tBA. In total, 100 equiv of each monomer was used to synthesize diblock copolymer. M_n and MWD of the diblock macro-CTAs for the synthesis of triblock copolymers were as follows: (a) $M_n = 12\,600$, $M_w/M_n = 1.30$; (b) $M_n = 18\,700$, $M_w/M_n = 1.18$; (c) $M_n = 19\,000$, $M_w/M_n = 1.13$; (d) $M_n = 11\,500$, $M_w/M_n = 1.09$; and (e) $M_n = 11\,000$, $M_w/M_n = 1.11$ (M_n was given in g mol^{-1}).

Scheme 12 Chemical structures of diblock copolymers containing a PNVP segment prepared by SBRP and BIRP (M_n was given in g mol^{-1}).

with St was inefficient, that to MMA proceeded smoothly in the presence of AIBN to give highly controlled PNVP-*block*-PMMA with a narrow MWD ($M_w/M_n = 1.18$). Since these block copolymers comprise hydrophobic PS or PMMA and hydrophilic PNVP blocks, their physical properties will be of great interest.

New block copolymers comprising an alternative copolymer consisted of acrylates and vinyl ethers as a block segment were also synthesized.¹¹⁸ For example, polymerization of organotellurium-PBA macro-CTA prepared from **Te-1** with a mixture of BA and IBVE afforded a block copolymer poly[BA-*block*-(BA-*alt*-IBVE)] with controlled MWD ($M_n = 27700 \text{ g mol}^{-1}$, $M_w/M_n = 1.22$) (Scheme 13a). The MF of IBVE in the second block was 0.44, suggesting that highly alternating copolymerization occurred during the formation of the second block.

An alternating copolymer was also used as a macro-CTA. Organotellurium-poly(BA-*alt*-IBVE) macro-CTA ($M_n = 3900 \text{ g mol}^{-1}$, $M_w/M_n = 1.20$,

$\text{MF}_{\text{IBVE}} = 0.49$) was prepared by copolymerizing BA (20 equiv) and IBVE (100 equiv) in the presence of **Te-1**. Since about 80 equiv of unreacted IBVE remained in the reaction mixture, addition of *t*BA (50 equiv) reinitiated the copolymerization, affording poly[(BA-*alt*-IBVE)-*block*-(*t*BA-*co*-IBVE)] with a narrow MWD ($M_n = 11700 \text{ g mol}^{-1}$, $M_w/M_n = 1.20$) (Scheme 13b).

As vinyl ethers do not homopolymerize, the group transfer radical addition reaction of poly(meth)acrylate prepared by LRP to vinyl ethers can be used for selective end-group transformation reaction (Scheme 14). The resulting adduct was used for a macro-CTA for living cationic polymerization of vinyl ethers in the presence of Lewis acid giving poly[(meth)acrylate-*block*-(vinyl ether)].¹²⁶

This one-pot, three-step reaction was applied to the combination of BA and IBVE, BA and *n*-butyl vinyl ether, BA and *n*-octyl vinyl ether, and MMA and IBVE. Desired block copolymers with M_n ranging from 8000 to 20 000 g mol^{-1} with

Scheme 13 Synthesis of block copolymers containing a poly(BA-*alt*-IBVE) segment (M_n was given in g mol^{-1}).

Scheme 14 Synthesis of “hybrid” block copolymer by successive living radical and living cationic polymerization reactions.

controlled MWD ($M_w/M_n = 1.21\text{--}1.46$) were successfully synthesized. Starting from a bifunctional CTA **Te-14**, a symmetrical ABA-triblock copolymer, poly(IBVE-*block*-BA-*block*-IBVE), was successfully synthesized by TERP of BA, the radical addition reaction to IBVE, and living cationic polymerization of IBVE by employing $\text{BF}_3\cdot\text{OEt}_2$ as a Lewis acid (Scheme 15).

(Meth)acrylates and vinyl ethers are orthogonal monomer families under radical and cationic polymerization conditions, and they cannot be polymerized under cationic and radical conditions, respectively. However, a selective chain end transformation via a radical-mediated tellurium-group transfer addition reaction of poly(meth)acrylate macro-CTA to vinyl ethers alternates the reactivity of ω -polymer-end group and enables the synthesis of “hybrid” block copolymer by successive living radical and living cationic polymerizations.

Moreover, macro-CTAs prepared by alternating copolymerization of (meth)acrylates and vinyl ethers were used as initiators for living cationic polymerization (Scheme 16).¹²⁶ Since excess amount of vinyl ethers was employed over (meth)acrylates to achieve highly alternating monomer sequence, polymer-end unit is derived from vinyl ethers. Therefore, the copolymer formed by LRP was directly used as a macro-CTA for the cationic polymerization. For example, an alternating copolymer-macro-CTA ($M_n = 3900 \text{ g mol}^{-1}$, $M_w/M_n = 1.19$, $\text{MF}_{\text{IBVE}} = 0.50$) was prepared by TERP of TFEA (20 equiv) and IBVE (200 equiv) in the presence of **Te-1**. After the reaction mixture was diluted with CH_2Cl_2 , the addition of $\text{BF}_3\cdot\text{OEt}_2$ triggered the living cationic polymerization of IBVE. Desired block copolymer poly[(TFEA-*alt*-IBVE)-*block*-IBVE] was

Scheme 15 Synthesis of a ABA-triblock copolymer by successive living radical and living cationic polymerization reaction starting from a bifunctional CTA **Te-14** (M_n was given in g mol^{-1}).

formed with a controlled macromolecular structure ($M_n = 23300 \text{ g mol}^{-1}$, $M_w/M_n = 1.32$).

3.8 End Group Transformation

A characteristic feature of the SBRP, BIRP, and TERP is the versatility of the transformations that can be carried out on the polymer-end groups. Since polymer-end radicals are easily generated from the organoheteroatom dormant species, several polymer-end group transformations mediated by radical species have been developed. While organoiodine polymer-end group in IRP including RTCP is expected to have similar reactivities to those in SBRP, BIRP, and TERP, its utilization has not been well studied yet.

Radical-mediated reduction of organoheteroatom ω -end groups is the simplest route to ω -protonated and deuterated polymers.^{21,25,27,30} For example, treatment of PMMA **7** bearing dimethylstibanyl group with tributyltin hydride and deuteride gave end protonated deuterated PMMA **8** and **8-d**, respectively, in quantitative conversion through the polymer-end radical species (Scheme 17a).¹⁰⁶ Structures of **8** and **8-d** were unambiguously determined by Matrix Assisted Laser Desorption Ionization Time of Flight (MALDI-TOF) mass (Figure 2) and ^2H NMR spectroscopy. Not only tin hydrides, which pose environmental concerns, but arylthiols can also be used as reducing agents.¹²⁷

When **7** was treated with ethyl [(tributylstannyl)methyl]acrylate (**9**)¹²⁸ in the presence of AIBN, ω -vinylidene functionalized PMMA **10** was formed (Scheme 17b).^{27,106} Structurally related ω -vinylidene functionalized PMMA **11** was also formed when PMMAs prepared using SBRP, BIRP, and TERP were treated with 2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPO) under thermal or photochemical conditions (Scheme 17c).¹⁰⁶

The formation of **11** is due to the abstraction of a β -hydrogen adjacent to the radical center by TEMPO. The same protocol could be used for the synthesis of ω -vinylidene functionalized polymethacrylonitrile. The complete end group transformation must be due to the high efficiency of radical generation by direct carbon–heteroatom homolysis.

The selective ω -end group transformation combined with the use of functional CTAs, such as **Sb-8** and **Sb-9**, have led to the synthesis of structurally well-controlled telechelic polymers,¹²⁹ which possess reactive functional group(s) at both polymer ends.²³ For example, PS **12**, which possesses an alkene functionality at the α -polymer-end prepared from **Sb-8** and St, was heated with allylstannane **9** in the presence of AIBN at 80°C , giving telechelic polymer **13** as the sole product (Scheme 18a). Aerobic oxidation of an organostibanyl group to a hydroxyl group has been reported,¹³⁰ and application of this procedure to **12** resulted in the selective formation of ω -hydroxylated PS **14** (Scheme 18b). The different functional groups at the α -polymer and ω -polymer ends of these PSs should be useful for further selective synthetic transformations.

The reaction of living polymers prepared using RAFT with an excess amount of AIBN has recently been reported to form the bis-functionalized polymers by Perrier *et al.*,¹³¹ and this method has been applied to organostibine-substituted living polymers (Scheme 19).²³ For example, the reaction of azo-initiator **15** with tetramethyldistibine gave CTA **Sb-9** (Scheme 19). Then, organostibine-PS **16**, which was prepared using SBRP of St with **Sb-9**, was treated with 40 equiv of **15** to give α,ω -bisfunctionalized PS **17**. These results indicate that not only homotelechelic polymers but also heterotelechelic polymers, which possess different functional groups at their α -polymer and ω -polymer ends, can be synthesized by

Figure 2 MALDI-TOF mass spectra of (a) end-protonated polystyrene **8** and (b) end-deuterated polystyrene **8-d**. The molecular ions were observed as silver ion adducts ($m/z = (M + Ag)^+$). [Reprinted from Ref. 30. © American Chemical Society, 2003.]

arbitrary choice of the azo-initiator for preparation of the CTA and the subsequent ω -polymer-end transformation.

Organotellurium compounds are excellent precursors not only for carbon-centered radicals but also for carbanions and carbocations.^{132–134} Once

such ionic species are selectively generated from the polymer-end organotellurium compounds, they are highly effective intermediates for the end functionalization (Scheme 20). Tellurium–lithium transmetalation^{135,136} was achieved by the treatment of organotellurium-PS **18** possessing

Scheme 17 Radical-mediated transformations of heteroatom-substituted PMMA polymer-end.

methyltellanyl group at the polymer end with butyllithium to give benzyl lithium **19**, which was trapped with an electrophile, such as carbon dioxide, giving carboxylic acid functionalized PS **20**.²⁷ The carboxylic acid was further transformed

to different functional groups using standard techniques, such as esterification. Treatment of **18** with phenyltellanyl triflate in the presence of 1,3,5-trimethoxybenzene afforded Friedel–Crafts product **22** through benzilic cation **21**.¹³⁷

Scheme 20 Carbanion- and carbocation-mediated transformation of PS-TeMe.

Since carbanions occupy a central position in organic synthesis,^{138,139} the end-group modification via a polymer-end anionic species, for example, **19**, is an attractive method. However, carbanions are usually incompatible with polar functional groups that are often present in polymers prepared by LRP. Kayahara *et al.* recently reported that organostibines and organobismuthines are highly reactive to stibine–metal and bis-muthine–metal exchange reaction, respectively, and that the exchange reaction proceeds much faster than the reaction of organometallic species reacting to polar functional groups. The method was applied to the end group modification of living polymers prepared by SBRP and BIRP.¹⁰⁴ For example, the exchange reaction between organostibine- and organobismuthine-PMMA **23** prepared by SBRP and BIRP, respectively, and *n*BuLi selectively occurred to give polymer-end anion **24**. Treatment of **24** with various electrophiles, for example, carbon dioxide selectively gave ω -carboxylated PMMA **25** in quantitative conversion (Scheme 21a). While

PMMA **25** ($M_n \sim 3000 \text{ g mol}^{-1}$) contains about 30 ester groups, the exchange reaction exclusively occurs at the polymer-end group. The exchange reaction with tetraalkylzincates, Me_4ZnLi_2 ^{140–142} and $t\text{Bu}_4\text{ZnLi}_2$,^{143–145} and $i\text{PrMgCl}\cdot\text{LiCl}$ ^{146,147} also took place chemoselectively leaving ester groups intact.

The exchange reaction can also be applicable for polyacrylates and polyacrylamides possessing acidic hydrogen in the main chain as well as the side chain by employing $t\text{BuZnLi}_2$. For example, polymer-end dimethylstibanyl group in PNIPAM **26** was successfully transformed to the corresponding anionic species by $t\text{BuZnLi}_2$ in DMF without protection of the amide protons. Subsequent addition of biotin chloride exclusively afforded ω -biotinylated PNIPAM **27**. The structure of **27** was unambiguously confirmed using ^1H NMR and MALDI-TOF mass spectroscopy analyses. PNIPAM is a thermoresponsive polymer and possesses lower critical solution temperature (LCST) in water. On the other hand, biotin is a good ligand for proteins, such

Scheme 21 Synthesis of ω -functionalized PMMA through chemoselective heteroatom–lithium exchange reaction.

as avidin and streptavidin. Therefore, this polymer and its analogs would make it possible to thermally modulate the properties of biomaterials for biological applications.¹⁴⁸

As the reactivity of organotellurium and organoiodine compounds toward the exchange reaction is very similar to organostibine and organobismuthine compounds,¹⁰⁴ the same type of anion-mediated transformations of organotellurium polymer-end group would also be possible for the living polymers prepared by TERP and IRP.

4 MECHANISM

4.1 Activation/Deactivation Mechanism of Dormant/Radical Species

Studies on the kinetics involved in the activation and deactivation of dormant species have revealed the existence of two mechanisms: reversible termination (RT, Scheme 22a) and degenerative chain transfer (DT, Scheme 22b).^{24,29,116} Although NMP and ATRP proceed exclusively via the RT mechanism and RAFT via the DT mechanism, TERP, SBRP, and BIRP proceed through the two mechanisms. Involvement of the two mechanisms makes these LRP methods unique, and it is the origin of three

(a) Reversible termination (RT) mechanism

(b) Degenerative transfer (DT) mechanism

Scheme 22 Activation/deactivation mechanisms involved in SBRP, BIRP, TERP, and IRP.

polymerization conditions described in the previous section.

The first-order rate constant for the activation of the dormant species via RT (k_d) and the second-order rate constant for the activation via DT (k_{ex}) in SBRP,^{21,24} BIRP,²⁵ TERP,^{29,33,116} and IRP¹⁴⁹ are summarized in Table 3. The rate constants of NMP¹⁵⁰ and RAFT¹⁵¹ are also listed as a reference. For example, the k_d and k_{ex} for TERP using the methyltellanyl derivative ($X = \text{TeMe}$) at 60 °C in St polymerization are $1.2 \times 10^{-5} \text{ s}^{-1}$ and $5.7 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$. The activation energy of DT was also determined to be 30 kJ mol^{-1} , whereas that for RT of PS-TeMe is estimated to be around 120 kJ mol^{-1} from the BDE of polymer-end mimetic CTA **Te-11**. Therefore, DT is the predominant mechanism in TERP. Although the rate constants

^aThe k_d , k_{ex} , and k_p are the rate constants for reversible termination (Scheme 22a), degenerative transfer (Scheme 22b), and propagation, respectively. C_{ex} is the degenerative chain-transfer constant ($= k_{ex}/k_p$).

^bData obtained at 100 °C.

are affected by the heteroatom species and the substituents on the heteroatom, the contribution of the RT mechanism is always considerably smaller than that of the DT mechanism in SBRP, BIRP, TERP, and IRP. Therefore, once the initiating radical species have formed, they predominantly undergo the DT-mediated polymerization reaction in all cases.

Under condition A (Section 3.4), the initiating radicals are provided via the thermolysis of the heteroatom CTA. The high temperatures and long reaction times required for the polymerization are due to the high activation energy required for the thermolysis. The initiating radicals are generated from azo-initiators under mild thermal conditions under condition B, and the polymerization proceeds exclusively via the DT mechanism. Under condition C, direct carbon–tellurium bond photolysis occurs to afford the initiating radicals from the dormant species. Since photochemical reactions do not require heat, polymerization also proceeds at low temperatures exclusively via DT. It is worth noting that, as the rate of polymerization becomes slower at lower temperatures, heating is sometimes necessary to complete the polymerization within a reasonable timescale when monomers with low propagation rates are employed under conditions B and C.

When LRP proceeds by DT mechanism, MWD of polymers can be estimated using (1) under steady-state conditions without any side reactions leading to dead polymers, where DP_n , c , C_{ex} ($= k_{ex}/k_p$), k_{ex} , and k_p are the number-average degree of polymerization, monomer conversion, a DT constant, a rate constant for DT, and a rate constant for the propagation reaction, respectively¹:

$$M_w/M_n = 1 + 1/DP_n + (2/c - 1)/C_{ex} \quad (1)$$

Since k_p and DP_n are constant when the same monomer with the same targeted M_n are considered, a faster k_{ex} and thus a higher C_{ex} leads to higher MWD control of the resulting polymer.

High values of k_{ex} and C_{ex} were observed for dimethylstibanyl, diphenylstibanyl, dimethylbismuthanyl, and methyltellanyl polymer-end group in SBRP ($C_{ex} = 32$ –118), BIRP ($C_{ex} = 53$), and TERP ($C_{ex} = 17$) in St polymerization. These values are sufficiently high to achieve high MWD control. Although C_{ex} ($= 10$) of the butyltellanyl group is slightly smaller than that of the methyltellanyl group, it is still faster than that

of the iodine atom ($C_{ex} = 3.5$).¹⁴⁹ The DT of the phenyltellanyl, *p*-methoxyphenyltellanyl, and *p*-trifluoromethylphenyltellanyl group in St polymerization ($C_{ex} = 28$ –41) takes place much faster than that of methyltellanyl group and very similar to that of dimethylstibanyl and dimethylbismuthanyl groups.

Among the same methyl-substituted heteroatom groups, bismuth is the fastest followed by antimony and then tellurium for the DT reaction. The kinetic data are also consistent with the general trend that organostibine, such as **Sb-2** and **Sb-3**, and organobismuthine CTAs, such as **Bi-1**, show higher MWD control than organotellurium CTAs **Te-1** and **Te-7** do. The kinetic data are also consistent with the observed higher MWD control using CTAs **Te-3**–**Te-5** possessing aryl substituents than that using methyltellanyl derivative **Te-1**.

The DT of diphenylstibanyl group at PS polymer end in St polymerization ($C_{ex} = 118$) occurs faster than that of dimethylstibanyl group. However, the MWD control using diphenylstibanyl CTA **Sb-4** was lower than that using dimethylstibanyl CTA, such as **Sb-1**. The insufficient control of diphenylstibanyl group is attributed to the occurrence of frequent termination.¹⁵² The results indicate that the rate of DT is not the exclusive factor for the MWD control.

The kinetic parameters in the polymerization of MMA, methyl acrylate (MA), and VAc involving an organotellurium dormant species with a methyltellanyl group are also summarized in Table 3.¹¹⁶ The DT mechanism is the predominant activation mechanism in all cases. The rate of DT of PMMA polymer end radical with PMMA-TeMe dormant species takes place about two times slower than that of a PS polymer-end species, and the propagation rate of the MMA polymerization is about 2.5 times faster than that of St. Consequently, C_{ex} ($= 3.6$) of the MMA polymerization becomes about five times smaller than that of the St polymerization. This C_{ex} value is too small to yield PMMAs with narrow MWDs. The result is consistent with the fact that the MWD control of the TERP of MMA was not sufficient ($M_w/M_n > 1.35$), and the addition of ditellurides was required to yield PMMA with a narrow MWD ($M_w/M_n \approx 1.1$).²⁸

SBRP and BIRP of MMA gave PMMA with a low MWD ($M_w/M_n < 1.25$) without the addition of the cocatalyst. The results suggest that the C_{ex} values under SBRP and BIRP must be larger than that under TERP, as in the polymerization of St,

and that organostibines and bismuthines generally have a higher reactivity in the DT reaction than organotellurium compounds have.

The rate of propagation of MA is about 70 times faster than that of St. However, as the rate of DT of the MA polymer-end species is about 80 times faster than that of PS, the C_{ex} (=19) in MA polymerization was similar to that in St polymerization. The result is also consistent with the fact that the polymerization of acrylates usually gives resulting polymers with a low MWD ($M_w/M_n < 1.2$).

SBRP, TERP, and IRP of VAc afforded PVAc with a low MWD when the degree of polymerization was low, but the control decreased with the increase in the degree of polymerization due to the formation of H–H addition (Section 3.5.5 and Scheme 8). Kinetic experiments revealed that DT of the PVAc polymer-end radical species with head-to-tail (H–T) dormant species in TERP ($X = \text{TeMe}$) was very fast with $k_{\text{ex}} = 1.0 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.¹¹⁶ Although the propagation rate constant of VAc ($k_p = 9.5 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$) is relatively high, C_{ex} is 110, a value large enough to give PVAc with a narrow MWD. In contrast, k_{ex} of the H–H dormant species ($X = \text{TeMe}$) was about 100 times slower than that of the H–T adduct ($C_{\text{ex}} = 1.2$), indicating that the activation from the H–H adduct was insufficient. Therefore, the H–H adduct virtually behaves as a dead polymer and is gradually accumulated in the reaction mixture as the polymerization progressed. Consequently, the MWDs gradually increased with an increase in monomer feed.

Although RAFT also proceeds by DT polymerization,^{19,20} the microscopic energy profiles of the DT in RAFT are completely different from those of SBRP, BIRP, TERP, and IRP as schematically shown in Figure 3. The DT in RAFT proceeds stepwise with the addition of radical P to thiocarbonyl compound **28** (a RAFT reagent) to form intermediate radical **29** (Figure 3a). Subsequent fragmentation of the S–P' bond in **29** generates RAFT reagent **28'** and radical P'. All the elementary processes are reversible, and the addition of radical P' to **28'** also generates radical P and **28** through intermediate **29**.¹⁵³ Although the lifetime of **29** must be short in order to minimize unwanted radical–radical termination process, the cross-termination involving **29** occurs as ascertained by Monteiro and de Brouwer¹⁵⁴ and Fukuda and coworkers.^{155,156} This chain breaking reaction causes the rate retardation observed in acrylate

Figure 3 Hypothetical reaction coordinate of DT in (a) RAFT and (b) TERP. The lines in gray show the energy diagram when less stabilized radical P and P' are involved. [Reprinted from Ref. 93. © American Chemical Society, 2009.]

polymerization, especially when phenyl-substituted RAFT CTA ($Z = \text{Ph}$) was used. Stability of **29** is strongly affected by Z substituent because it directly attaches to the radical center, while effects of P and P' radicals on **29** are marginal. When the same Z group is considered, relative stability and, thus, concentration of **29** increases as the polymer-end radical P and P' become less stable as shown by the gray line. This enhances the probability of **29** undergoing the chain breaking reaction. Therefore, appropriate choice of Z group is necessary depending on the monomer families being polymerized so as to undergo efficient degenerative transfer reaction.

In sharp contrast, the DT in TERP proceeds through hypervalent tellurium intermediate or transition state **31**, which forms by the reaction of radical P with organotellurium dormant species **30** to generate radical P' and new dormant species **30'** (Figure 3b). Although the existence of a trivalent tellurium radical intermediate is still a controversial issue,^{89, 157–159} the intermediate, if any, should

Table 4 Kinetic parameters for the deactivation of polymer-end radicals by ditelluride¹⁰⁵ and metaliodide¹⁶³ “cocatalyst.”^a

Monomer	Cocatalyst	<i>T</i> (°C)	<i>K</i> _{da} (M ⁻¹ s ⁻¹)	<i>k</i> _p (M ⁻¹ s ⁻¹)	<i>C</i> _{da}
St	(MeTe) ₂	60	3.4–6.8 × 10 ⁵	3.4 × 10 ²	1000–2000
	GeI ₄	80	9.0 × 10 ⁵	6.6 × 10 ²	1400
	SnI ₄	80	5.7 × 10 ⁵	—	860
	NIS	80	4.3 × 10 ⁵	—	650
	Tolyl-GeI ₃	80	2.5 × 10 ⁵	—	380
	PI ₃	80	1.2 × 10 ⁵	—	180
MMA	(MeTe) ₂	60	1.2–2.4 × 10 ⁵	8.3 × 10 ²	150–290
	Tolyl-GeI ₃	70	3.1 × 10 ⁷	1.1 × 10 ³	30 000

^aThe *k*_{da} and *k*_p are the rate constants for deactivation of polymer-end radical (Scheme 23) and propagation, respectively. *C*_{da} refers to the deactivation constant (= *k*_{da}/*k*_p).

be very close in energy to the transition state. Therefore, the DT in TERP virtually proceed in a concerted manner, and involvement of a long-lived intermediate, which may cause unwanted side reactions, is unlikely. In addition, since the DT process becomes faster when less stable polymer-end radicals are involved as shown by the gray line, CTAs with the same Z group can be used for controlling LRP of various families of monomers. Energy profiles of SBRP, BIRP, and IRP should be very similar to TERP, though more experimental and theoretical investigations are needed.^{160,161}

The contribution of RT is small compared to DT, but it plays a crucial role in BIRP and TERP under condition A (Tables 2 and 3).¹¹⁶ The rate of RT reaction of PS-TeMe is very similar to that of NMP, PS-TEMPO,¹⁵⁰ and the results are consistent with the similarity of BDEs of structurally related organotellurium and nitroxide compound²⁷ and the similarity of the polymerization condition of TERP under condition A and NMP. The results indicate that CTAs in BIRP and TERP also serve as radical initiators. As the rate of thermal dissociation of organobismuth compounds is about two times faster than that of organotellurium compounds, the former is the best radical initiator among the heteroatom compounds.

4.2 Role of Diheteroatom Compounds

Addition of distibines, ditellurides, and various inorganic and organic cocatalysts in SBRP, TERP, and IRP, respectively, is effective for increasing MWD control in St and methacrylate polymerization (Section 3.5.1).^{23,28} Thiobismuthine **Bi-S** is also

effective for the controlled synthesis of ultrahigh molecular weight PSs and polyacrylates.

Kinetic studies to elucidate the effect of ditellurides have revealed that polymer-end radicals are effectively deactivated by ditelluride via a homolytic substitution reaction to form the dormant species (Table 4, Scheme 23a).¹¹⁶ The second-order rate constant (*k*_{da}) for the deactivation of PS polymer-end radical by dimethylditelluride at 60 °C is 3.4–6.8 × 10⁵ M⁻¹ s⁻¹, which corresponds to the deactivation constant *C*_{da} (= *k*_{da}/*k*_p) of 1000–2000. These values are about 100 times faster than the rate constant of DT (*k*_{ex}) and the *C*_{ex} of PS polymer-end radical with PS dormant species as shown in Table 3. The *k*_{da} for the deactivation of PMMA polymer-end radical by dimethylditelluride at 60 °C is 1.2–2.4 × 10⁵ M⁻¹ s⁻¹ (*C*_{da} = 150–290), the value of which is also 40–80 times faster than the DT rate constant *k*_{ex} of PMMA polymer-end radical by PMMA dormant species. These values are high enough to obtain PS and PMMA with narrow MWD.

The liberated tellanyl radical reacts with an organotellurium dormant species to regenerate a polymer-end radical and ditelluride. Therefore, the deactivation/activation mechanism of the dormant/radical species completely changes from the DT to the ditelluride trapping by the addition of sub-stoichiometric amount of ditelluride. The occurrence of more frequent deactivation/activation of the dormant/radical species is responsible for the increased MWD control by the addition of ditelluride.

Despite the high reactivity of tellanyl radical to organotellurium dormant species, it is virtually inert to monomer and does not initiate new polymer chains.¹⁶² If it did, the observed high controllability would not be realized. These seemingly conflicting reactivities of tellurium-centered radicals also play

Scheme 23 Deactivation mechanism of polymer-end radical P by diheteroatom compounds.

crucial roles in the control of MWD in TERP in the presence of ditellurides.

Inorganic and organic cocatalysts used in RCTP also serve as a deactivator for the polymer-end radicals leading to a dormant species (Scheme 23b).¹⁶³ The rate constants k_{da} of GeI_4 , SnI_4 , NIS, TolyI- GeI_3 , and PI_3 are also summarized in Table 4. GeI_4 showed most active cocatalyst for the deactivation among these cocatalysts, and the k_{da} for the deactivation of PS polymer-end radical by GeI_4 at 80 °C is $9.0 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$. The deactivation constant is $C_{da} = 1400$, which is 400 times faster than the C_{ex} of PS-I dormant species and is very similar to the capping reaction by dimethyl ditelluride. The C_{da} of SnI_4 , NIS, TolyI- GeI_3 , and PI_3 are 860, 650, 380, and 180, respectively, and these values are sufficiently high to obtain PS with narrow MWD. The k_{da} for the deactivation of PMMA polymer-end radical by TolyI- GeI_3 at 80 °C is $3.1 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ ($C_{da} = 30\,000$), which is extremely fast and sufficiently high enough to control the polymerization of MMA.

When cocatalysts having X-H (X = heteroatom and carbon) are used, such as phenol and carbon catalysts shown in Scheme 5, the X-H bond is transformed *in situ* to X-I bond on hydrogen abstraction of X-H by a radical generated from an initiator followed by the trapping of X radical by iodine source. Once the X-I compound forms, an equilibrium between the polymer-end radical/X-I and the dormant species/X radical is established.

When such X-H-type cocatalysts are used, the hydrogen serves as a reducing agent for radicals generated in the reaction mixture. In addition, when the amount of cocatalyst was increased, rate retardation of the polymerization was observed due to the cross-termination reaction of the X radical with a polymer-end radical.⁷⁶ Therefore, the amount of cocatalyst must be tuned to maximize the advantage of the cocatalyst.

Although there are no kinetic studies on the effects of distibines in SBRP, the increased MWD control in the presence of distibine can also be ascribed to the higher efficiency of the deactivation of the polymer-end radical by distibine via a homolytic substitution reaction (Scheme 22c). The effect on the control using distibine is more noticeable than ditelluride, and this may be attributed to the higher reactivity of distibine than ditelluride, as in the DT reaction of polymer-end dormant species (Section 4.1).²³ The observed rate retardation in the presence of distibine is likely to shift the equilibrium from the polymer-end radical to the dormant species. This shift is probably due to the low reactivity of the dimethylstibanyl radical compared to that of an organostibine dormant species. In such a case, the stibanyl radical may dimerize to a distibine. Cross-termination between the stibanyl radical and a polymer-end radical may also occur to regenerate a dormant species.

The role of thiobismuthine **Bi-S** is to react reversibly with the polymer-end radical to

generate an organobismuthine dormant species and 2,6-dimesitylphenylthiyl radical (Scheme 22d).¹⁶⁴ The bulky 2,6-dimesitylphenyl group attached to the sulfur atom may prevent the addition of thiyl radicals to the vinyl monomers generating a new polymer chain, as thiyl radicals are reactive toward alkenes.¹⁶⁵ Since thiyl radicals are highly reactive toward organobismuthines,¹²⁷ the liberated thiyl radical reacts with the organobismuthine dormant species to regenerate the polymer-end radical P and Bi-S.

5 SYNTHESIS OF FUNCTIONAL POLYMERS BY TERP

5.1 Thermosensitive Micelles

Yusa *et al.*³² have reported the synthesis of diblock copolymers composed of PNIPAM and PNVP and their solution properties in water. The synthesis was achieved by successive TERP of NIPAM and NVP using **Te-2** as a CTA. Since the consumption of NIPAM was quantitative, no purification was necessary before the addition of NVP. By changing the amount of each monomer, diblock copolymers with different block lengths were also prepared in a controlled manner ($M_n = 17\,000$ – $36\,700$ g mol⁻¹, $M_w/M_n = 1.09$ – 1.15) (Figure 4a).

PNIPAM is a representative thermosensitive polymer and has a LCST in water,¹⁶⁶ and PNVP

is a water soluble polymer.^{167,168} Therefore, the block copolymers reversibly form micelles in water depending on the solution temperature (Figure 4b). Each block copolymer reversibly forms spherical core-corona micelles above T_a with unique aggregation numbers (300–27 000) depending on the block lengths of each segment.

Although there have been a number of reports concerning the synthesis of thermoresponsive block copolymers containing PNIPAM segment,^{169–171} this is the first example of the synthesis of diblock copolymer micelle comprising PNIPAM and PNVP. Since PNVP is a water soluble and biocompatible polymer, this block copolymer is a good candidate for several biological applications, such as in thermosensitive drug delivery vehicles.¹⁷²

The same diblock copolymer encapsulates gold nanoparticles in water via coordination of the PNVP block to the gold particle, as schematically shown in Figure 4b.¹⁷³ The polymer-coated gold nanoparticles show a temperature-dependent color change of the solution from pink to bluish-purple above the LCST of PNIPAM determined on the basis of the surface plasmon band. The polymer-coated gold nanoparticles may be separately dissolved in water when the temperature is below the LCST for the PNIPAM block. However, they may associate with each other due to hydrophobic interactions between the dehydrated PNIPAM blocks at temperatures above LCST, inducing a color change. This phenomenon may be applied to colloidal sensors.

Figure 4 (a) Chemical structure of thermoresponsive diblock copolymer PNIPAM-*block*-PNVP and (b) schematic illustration of the micellization of the block copolymer as a function of temperature and the formation of a polymer-coated gold nanoparticle (M_n was given in g mol⁻¹). [Reprinted from Ref. 32. © American Chemical Society, 2007.]

5.2 Polymer Monoliths

Kanamori and coworkers have reported that TERP of 1,4-divinylbenzene in the presence of poly(dimethylsiloxane) and 1,3,5-trimethylbenzene gave macroporous cross-linked polymeric gels (Figure 5a).¹⁷⁴ Well-defined macroporous monolithic dried gels with bicontinuous structures on the micrometer scale were obtained after removing poly(dimethylsiloxane) and 1,3,5-trimethylbenzene by simple washing and drying (Figure 5b). Inside the skeletons that comprise the macroporous structure, “skeletal pores” with various sizes on the nanometer scale were found. The controlled pore formations are based on polymerization-induced phase separation by spinodal decomposition in the course of the homogeneous network formation during LRP. An unreactive polymeric agent present in solution during the polymerization induces spinodal decomposition during gelation to give a

well-defined bicontinuous porous structure. Pore size and volume can be independently controlled by changing the starting composition.¹⁷⁵

Conventional free radical polymerization in the presence of a “porogen,” which is usually a poor solvent for the network-forming components and induces phase separation, is widely used for the preparation of porous polymeric materials (polymer monoliths).^{176–178} Polymer monoliths thus prepared have been applied especially as liquid-phase separation or reaction media.^{179,180} However, fine-tuning of the pore properties, such as pore size, volume, and morphology, is relatively difficult because the pores are formed between segregated microgel particles that aggregate at random. Since the more homogeneous macroporous morphology with a bicontinuous structure was obtained, this type of materials will improve liquid transport throughout the media and liquid-phase applications, such as chromatography and catalyst supports, are expected.

Figure 5 (a) Synthesis and (b) morphology of polydivinylbenzene (PDVB) gel prepared using TERP of 1,4-divinylbenzene. [Reprinted from Ref. 174. © American Chemical Society, 2009.]

The same group has also reported the synthesis of rigid cross-linked polyacrylamide monoliths with well-defined macropores derived from *N,N*-methylenebis(acrylamide) using TERP accompanied by spinodal decomposition with polyethylene oxide as a porogen.¹⁸¹ They are promising materials with highly hydrophilic polyacrylamide surfaces and have enough strength to withstand the surface tension arising from repetitive swelling and drying, which is inevitable in many applications. Kanamori *et al.* has also reported the synthesis of polymer monoliths with controlled pore properties using NMP of 1,4-divinylbenzene¹⁷⁵ and ATRP of 1,3-glycerol dimethacrylate.¹⁸² Therefore, the synthesis of polymer monoliths with controlled pore sizes is not limited to TERP. However, the synthetic advantages of TERP, such as high functional compatibility and high versatility of polymerizable monomer families, should be beneficial for the future design of new monoliths with various functionalities.

5.3 Adhesives, Dispersants, and Compatibilizers

Otsuka Chemical Co. recently announced that they had started selling several adhesives prepared using TERP (<http://chemical.otsukac.co.jp/advanced/about01.html>). Although detailed polymer compositions and chain lengths are not shown, control of MWD and the distribution of the cross-linking functionality of the polymer is the key for improving the properties. For example, a model random copolymer formed by TERP with an M_w of 581 600 with a narrow MWD ($M_w/M_n = 1.24$), whereas a control polymer prepared by conventional radical copolymerization had a broad MWD ($M_w = 703\,800\text{ g mol}^{-1}$, $M_w/M_n = 3.44$). A model adhesive prepared from the model polymer by cross-linking reaction had about 10 times stronger holding power than a control adhesive prepared from the control polymer, although they had similar adhesive powers. The properties of adhesives, such as the adhesive power and the tack, are easily tuned by changing the composition of functional groups and/or chain lengths. Otsuka Chemical Co. has also succeeded in the development of polymer compatibilizers and pigment dispersants consisting of block copolymers prepared by TERP.

6 CONCLUSION

SBRP, BIRP, TERP, and RTCP are versatile and robust methods for the preparation of structurally well-controlled macromolecules. Characteristic features of these methods include wide applicability to the polymerization of a variety of monomer families, high functional group compatibility, and a strong ability for the syntheses of block copolymers and end-modified polymers. These features clearly demonstrate that SBRP, BIRP, TERP, and RTCP could rival current LRP methods for the preparation of functionalized macromolecules with well-defined structures.

The development of these polymerization methods also clarified the unique reactivities of heteroatom compounds under radical conditions, especially toward the DT reaction. The rate of the DT reaction can be highly tuned by changing the central heteroatom and also substituent on the heteroatom. In addition, several diheteroatom, inorganic, and organic cocatalysts show ultrafast reaction toward radical species and highly effective to increase MWD control. Since methods to control the radical reaction is limited so far, these findings will offer a new strategy for highly controlled radical reactions in both polymer and organic synthesis. With the aid of such basic understandings, one can create truly powerful and useful LRP method to overcome the scientific and technical problems hindering industrial applications of LRP.

Photoinduced Reactions of Radical Ions via Charge Separation

Shunichi Fukuzumi^{1,2} and Kei Ohkubo¹

¹Department of Material and Life Science, Graduate School of Engineering, Osaka University, ALCA, Japan Science Technology Agency (JST), Suita, Osaka, Japan and ²Department of Bioinspired Science, Ewha Womans University, Korea

1 INTRODUCTION

Free radicals are highly versatile and reactive intermediates, allowing many synthesis to be carried out under relatively mild conditions in chemical and biological systems (1).^{1–5} However, the high reactivity of free radicals usually results in low selectivity (2) and (3). Thus, it has been difficult to utilize reactions between free radicals for selective bond formation^{1–5}:

In contrast to neutral free radicals, reactions of radical ions are well controlled by charges: radical cations are expected to react selectively with radical anions (4) as compared with reactions of radical ions with the same charge (5) and (6):

Thus, reactions between radical cations and radical anions have profound fundamental and

synthetic interest for selective bond formation.^{6–13} Radical cations and radical anions are formed using electron donor–acceptor-linked molecules, because the photoexcitation results in the formation of the radical ion pair, which can oxidize and reduce substrates to generate the corresponding radical cations and radical anions, respectively.^{14–17} Radical cations ($X^{\bullet+}$) and radical anions ($Y^{\bullet-}$) thus produced may couple selectively to produce the coupling products ($X-Y$) (4) in competition with back electron transfer from $Y^{\bullet-}$ to $X^{\bullet+}$.

Extensive studies have so far been devoted to mimic the function of the photosynthetic reaction center by developing electron donor–acceptor-linked molecules, which undergo a cascade of electron-transfer steps leading to long-range charge separation with prolonged lifetime of the charge-separated (CS) state.^{18–40} In a view of synthetic feasibility and their applications, it is important to develop electron donor–acceptor dyads in which the CS states have long lifetimes without losing energy by multistep electron-transfer processes.

This article focuses on reactions of radical ions produced by electron-transfer reactions of the CS state of electron donor–acceptor dyads (D–A) as shown in Scheme 1. First an electron donor–acceptor dyad capable of efficient photoinduced electron transfer to produce a long-lived CS

Scheme 1 Radical coupling reaction of X^{*+} and Y^{*-} produced by electron-transfer reactions of substrates (X and Y) with the CS state of an electron donor–acceptor dyad (D–A).

state ($D^{*+}-A^{*-}$) is described. Then, the long-lived CS state is utilized for generation of radical cations (X^{*+}) and radical anions (Y^{*-}), which are coupled to afford the coupling products (X–Y) (Scheme 1). Radical cations can also be converted to the corresponding neutral radicals by deprotonation, whereas radical anions can be converted to the corresponding neutral radicals by protonation. Thus, combination of deprotonation of radical cations and protonation of radical anions leads to facile reactions of neutral radicals. The reactions of radical cations, which are produced by electron-transfer reactions of the CS state of an electron donor–acceptor dyad, with nucleophiles are also described in this article.

2 FORMATION OF LONG-LIVED CHARGE-SEPARATED STATES

In order to produce radical ions by electron-transfer reactions with a CS state, the CS lifetime must be long enough to compete with back electron transfer to the ground state. The lifetime of the CS state has been reported to be elongated by decreasing the distance between the donor and acceptor in the dyads, which results in a decrease in the solvent reorganization energy of electron transfer.⁴¹ Among many electron donor–acceptor-linked molecules, an acridinium ion is the best candidate as a chromophore as well as an electron acceptor, because of the efficient electron self-exchange between the acridinium ion and the corresponding one-electron reduced radical^{7,42} and the high triplet excited energy.⁴³ Thus, an electron donor moiety (mesityl group) is directly connected at the 9-position of the acridinium ion to yield 9-mesityl-10-methylacridinium ion (Acr^+-Mes , Figure 1),⁴⁴ in which the solvent reorganization of electron transfer is minimized, because the overall charge remains the same in the charge-shift electron transfer with the short

Figure 1 Chemical structure and crystal structure of Acr^+-Mes .⁴⁴

linkage between the donor and acceptor moieties. Acr^+-Mes affords the electron-transfer state on photoexcitation with not only a much longer lifetime (e.g., 2 h at 203 K) and a high quantum yield close to unity (98%) but also a much higher energy (2.37 eV) than the natural system.⁴⁴

The rate of intramolecular electron transfer from the Acr^+ moiety to the Mes^{*+} moiety in the same Acr^+-Mes^{*+} molecule is highly temperature dependent and the lifetime of the electron-transfer state becomes almost infinite (10^{29} years extrapolated from the Arrhenius plot for BET rates) at 77 K in solid state.⁴⁴ Nuclear tunneling usually becomes more apparent at lower temperatures, but this seems not to be the case for Acr^+-Mes^{*+} . The X-ray crystal structure of Acr^+-Mes in Figure 1 exhibits that the dihedral angle is perpendicular between the Mes and Acr^+ moieties of Acr^+-Mes .⁴⁴ In such a case, the orbital interaction between the donor and acceptor moieties is minimized. This is the key point to attain the long lifetime of the electron-transfer state. The simple molecular dyad (Acr^+-Mes) capable of fast photoinduced electron transfer but relatively slow back electron transfer to the ground state has clear advantages with regard to synthetic feasibility and its application as an organic photocatalyst.⁴⁵

The electron-transfer state of Acr^+-Mes has both strong oxidizing and reducing ability that would never be attained by the excited state of the electron acceptor moiety.^{44,46} However, there have been some reports on possible formation of the triplet excited state of the acridinium ion moiety rather than the electron-transfer state (Scheme 2).^{47–51} It was reported that the photoexcitation of 9-(1-naphthyl)-10-methylacridinium ion (Acr^+-1NA) resulted in the formation of the

Scheme 2 Reaction course of Acr^+-Mes on photoexcitation.

Scheme 3 π -Dimer formation of the electron-transfer state of Acr^+-1NA with the ground state of Acr^+-1NA .

triplet excited state, because of the absence of the transient absorption due to the radical cation at 700 nm.^{52–54} The reason why the electron-transfer state of Acr^+-1NA was overlooked was later shown by clear cut evidence of the formation of the electron-transfer state (NOT the triplet excited state) of Acr^+-1NA , which forms the π -dimer radical cation complex with the ground state of Acr^+-1NA (Scheme 3).⁵⁵ The nanosecond laser excitation of a deaerated acetonitrile (MeCN) solution of Acr^+-1NA at 355 nm resulted in the appearance of the new absorption band at 1050 nm due to the naphthalene π -dimer radical cation as shown in Figure 2a.⁵⁵ The equilibrium between monomer naphthalene radical cation and dimer naphthalene

radical cation is observed in intermolecular photoinduced electron transfer from naphthalene to the singlet excited state of 10-methylacridinium ion ($^1\text{AcrH}^{+*}$) as shown in Figure 2b.⁵⁵ When the concentration of naphthalene is 10 mM, the transient absorption due to monomer radical cation of naphthalene is clearly seen at 700 nm together with the near-infrared (NIR) absorption at 1050 nm due to the dimer naphthalene radical cation (Figure 2b). When the concentration of naphthalene is increased to 100 mM, the transient absorption at 700 nm due to monomer radical cation of naphthalene disappears, accompanied by an increase in the absorbance at 550 and 1050 nm due to the naphthalene π -dimer radical cation (Figure 2b). The

Figure 2 Transient absorption spectra of (a) Acr^+-1NA ($5.0 \times 10^{-5}\text{ M}$) and (b) AcrH^+ ($3.0 \times 10^{-5}\text{ M}$) with 10 mM (●) and 100 mM (○) of naphthalene in deaerated MeCN at 298 K taken at 2 μs after laser excitation at 355 nm.⁵⁵

broad absorption band in the NIR region due to the π -dimer radical cation was also clearly observed in the case of Acr^+-Mes .⁵⁵ This is different from the band at 960 nm due to the T–T absorption of 9-phenylacridine.^{46,56–58} The formation of stable π -dimer radical cations and anions of aromatic compounds has been well known as a result of π -bonding of neutral π -compounds with the radical cations and radical anions, respectively.^{59–66}

The light-harvesting capability of Acr^+-Mes is significantly improved by assembling Acr^+-Mes molecules on Au nanoclusters ($\text{Mes}-\text{Acr}^+-\text{PhS}-\text{AuC}$) as shown in Scheme 4.⁶⁷

The $\text{Mes}-\text{Acr}^+-\text{PhS}-\text{AuC}$ nanocluster was prepared by the coupling between the functional molecules and Au nanoclusters. Carboxyl-terminated $\text{Mes}-\text{Acr}^+-\text{COOH}$ ^{67,68} is directly coupled to 4-mercaptophenol-functionalized Au nanoclusters ($\text{PhS}-\text{AuC}$) in the presence of *N,N'*-diisopropylcarbodiimide and 4-(*N,N*-dimethylamino)pyridinium-4-toluene-sulfonate as the standard coupling agents (Scheme 4).⁶⁷ The reference compound ($\text{Mes}-\text{Acr}^+-\text{COOPh}$) was synthesized by condensation of $\text{Mes}-\text{Acr}^+-\text{COOH}$ and phenol.⁶⁷

Femtosecond laser excitation of $\text{Mes}-\text{Acr}^+-\text{PhS}-\text{AuC}$ at 420 nm results in appearance of a transient absorption band at 490 nm and a broad transient absorption band in the NIR region as shown in Figure 3a.⁶⁷ Such a broad NIR band is assigned to the π -dimer radical

cation of the electron-transfer state of $\text{Mes}-\text{Acr}^+$ ($\text{Mes}^{*+}-\text{Acr}^+-\text{PhS}-\text{AuC}$) with the neighboring $\text{Mes}-\text{Acr}^+$ molecule. This is made possible by the close proximity of $\text{Mes}-\text{Acr}^+$ molecules on AuC via an intramolecular π – π interaction on photoinduced electron transfer from the Mes moiety to the singlet excited state of the Acr^+ moiety. In contrast to this, no transient absorption band in the NIR region was observed in the case of the reference compound ($\text{Mes}-\text{Acr}^+-\text{COOPh}$), when only the transient absorption band at 490 nm due to the electron-transfer state of $\text{Mes}-\text{Acr}^+-\text{COOPh}$ ($\text{Mes}^{*+}-\text{Acr}^+-\text{COOPh}$) is observed at 10 ps (Figure 3b).⁶⁷ The π -dimer radical cation of $\text{Mes}^{*+}-\text{Acr}^+-\text{COOPh}$ with $\text{Mes}-\text{Acr}^+-\text{COOPh}$ was formed by the intermolecular reaction at 10 μs , in sharp contrast to intramolecular formation of the π -dimer radical cation at 1 ps as shown in Figure 3a.⁶⁷ Thus, the photoexcitation of gold nanoclusters (AuC) functionalized with $\text{Mes}-\text{Acr}^+$ resulted in rapid formation of the electron-transfer state ($\text{Mes}^{*+}-\text{Acr}^+$) to produce the π -dimer radical cation with the neighboring $\text{Mes}-\text{Acr}^+$ molecule on AuC, whereas such π -dimer radical cation formation occurs at much slower timescale for the reference compound ($\text{Mes}-\text{Acr}^+-\text{COOPh}$) by the intermolecular reaction between $\text{Mes}^{*+}-\text{Acr}^+-\text{COOPh}$ and $\text{Mes}-\text{Acr}^+-\text{COOPh}$.

Scheme 4 Preparation of 9-mesitylacridinium ion-monolayer-protected gold nanoclusters ($\text{Mes-Acr}^+\text{-PhS-AuC}$).⁶⁷

Figure 3 Transient absorption spectra observed in femtosecond laser flash photolysis ($\lambda_{\text{ex}} = 420 \text{ nm}$) of (a) $\text{Mes-Acr}^+\text{-PhS-AuC}$ at 2 and 500 ps and (b) $\text{Mes-Acr}^+\text{-COOPh}$ at 10 and 500 ps in MeCN at 298 K.⁶⁷

Immobilization of $\text{Acr}^+\text{-Mes}$ molecules in a solid porous framework provides a wide range of potential applications, including as solid-state photocatalysts and in electrical devices. Periodic mesoporous organosilicas (PMOs) prepared

by surfactant-directed self-assembly of bridged organosilane precursors ($(\text{R}'\text{O})_3\text{Si-R-Si}(\text{OR}')_3$, R: organic bridging group) have been used to immobilize $\text{Acr}^+\text{-Mes}$ (Scheme 5).⁶⁹ PMOs with a high surface area are promising candidates as

Scheme 5 Synthetic route for the preparation of Mes-Acr⁺ organosilane precursor **1** and mesostructured organosilica. (a) NaH, MOMCl, dimethylformamide (DMF); (b) MesMgBr, tetrahydrofuran; (c) HCl aq; (d) HSi(OEt)₃, NEt₃, *n*-Bu₄NI, [Rh(cod)(CH₃CN)₂]BF₄, DMF; (e) MeOTf, CH₂Cl₂ (X = OTf); (f) Brij76, HCl aq, EtOH.⁶⁹

solid-state functional materials, because their function and morphology can be readily controlled by appropriate selection of organic bridges (–R–) within the framework.^{70–77} The mesostructured materials were successfully obtained from the newly designed precursor **1** (Scheme 5) without dilution of the scaffold silica sources (e.g., tetraethoxysilane).⁶⁹ The Acr⁺–Mes-bridged precursor **1** was prepared starting from commercially available 2,7-dibromoacridone **2** in 74% overall yield (five steps) (Scheme 5). Photoinduced electron transfer within the Acr⁺–Mes–silica hybrid framework was demonstrated to afford the electron-transfer state over a microsecond timescale.⁶⁹

The following sections describe the development photocatalytic oxidation, cycloaddition, and bromination via the long-lived electron-transfer state of Acr⁺–Mes.

3 PHOTOOXYGENATION VIA ELECTRON TRANSFER

3.1 Photooxygenation of Anthracene via Radical Ion Coupling

As described above, photoexcitation of Acr⁺–Mes results in the formation of the electron-transfer state (Acr[•]–Mes^{•+}), which has an extremely long lifetime (e.g., 2 h at 203 K) as well as both highly oxidizing and reducing ability.^{44,78} In such a case, Acr⁺–Mes acts as an efficient electron-transfer photocatalyst for highly selective oxygenation of various substrates with O₂ via selective radical ion coupling of the donor radical cation and superoxide anion (O₂^{•–}) under visible light irradiation (vide infra).

Visible light irradiation (λ > 430 nm) of the absorption band of Acr⁺–Mes in an O₂-saturated

MeCN solution containing 9,10-dimethylantracene (Me_2An) results in the formation of oxygenation product, that is, dimethylepidioxanthracene ($\text{Me}_2\text{An-O}_2$) via efficient [4 + 2] coupling between the radical cation of 9,10-dimethylantracene ($\text{Me}_2\text{An}^{\bullet+}$) and $\text{O}_2^{\bullet-}$, which are produced by the electron-transfer oxidation of Me_2An and the electron-transfer reduction of O_2 with the electron-transfer state of Acr^+-Mes , respectively, as shown in Scheme 6.⁷⁸ Anthracene and 9-methylantracene also undergo the photocatalytic oxygenation by O_2 with Acr^+-Mes to afford the corresponding epidioxanthracenes (An-O_2 and MeAn-O_2 , respectively) under visible light irradiation.⁷⁸ Epidioxanthracenes are known to be formed by the reaction of anthracenes with singlet oxygen ($^1\text{O}_2$).⁷⁹ However, the rate constant of the reaction of $^1\text{O}_2$ with Me_2An ($2.4 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$) is much smaller than the rate constant of the radical coupling reaction of $\text{Me}_2\text{An}^{\bullet+}$ and $\text{O}_2^{\bullet-}$ ($1.7 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$) in MeCN at 298 K.⁷⁸ It was confirmed that no singlet oxygen emission was observed during the photocatalytic oxygenation of Me_2An in an O_2 -saturated CD_3CN .⁷⁸ Thus, $\text{Me}_2\text{An-O}_2$ is formed exclusively by the radical ion coupling between $\text{Me}_2\text{An}^{\bullet+}$ and $\text{O}_2^{\bullet-}$ rather than the reaction of Me_2An and $^1\text{O}_2$ as shown in Scheme 6.

In the case of anthracene, further photoirradiation results in the formation of anthraquinone as the final six-electron oxidation product via 10-hydroxyanthrone, accompanied by generation of H_2O_2 as shown in Scheme 7.⁷⁸ The photocatalytic oxygenation of anthracenes is initiated by photoexcitation of Acr^+-Mes , which results in the formation of the electron-transfer state ($\text{Acr}^{\bullet}-\text{Mes}^+$), followed by electron transfer from anthracenes to the Mes^+ moiety together with electron transfer from the $\text{Acr}^{\bullet}$ moiety to O_2 .^{44,78} The resulting anthracene radical cation undergoes radical coupling reactions with $\text{O}_2^{\bullet-}$ to produce the epidioxanthracene (An-O_2).^{44,78} The mechanism of the photocatalytic conversion of An-O_2 to 10-hydroxyanthrone is shown in Scheme 7.⁷⁸ The electron transfer from An-O_2 to the Mes^+ moiety of $\text{Acr}^{\bullet}-\text{Mes}^+$, produced on photoexcitation of Acr^+-Mes , results in the O–O bond cleavage of An-O_2 , followed by facile intramolecular hydrogen transfer to produce 10-hydroxyanthrone radical cation. Then the back electron transfer from $\text{Acr}^{\bullet}-\text{Mes}$ to 10-hydroxyanthrone radical cation yields 10-hydroxyanthrone to regenerate Acr^+-Mes . 10-Hydroxyanthrone is further oxidized to anthraquinone with $\text{Acr}^{\bullet}-\text{Mes}^+$, accompanied by reduction of O_2 to yield H_2O_2 (Scheme 7).

Scheme 6 Photocatalytic oxygenation of Me_2An by O_2 with Acr^+-Mes .⁷⁸

Scheme 7 Photocatalytic oxygenation of anthracene by O_2 with Acr^+-Mes .⁷⁸

3.2 Photocatalytic Oxygenation of Tetraphenylethylene to 1,2-Dioxetane

The Acr^+-Mes can also act as an efficient organic photocatalyst for the synthesis of 1,2-dioxetane of tetraphenylethylene (TPE), which would otherwise be impossible to synthesize.⁷⁹ 1,2-Dioxetanes have attracted considerable interest because of the key roles in chemiluminescence and bioluminescence,^{80–82} which have a broad range of biological, chemical, and medical applications.^{83–86} The most common preparation of 1,2-dioxetanes is through the formal [2 + 2] cycloaddition of singlet oxygen (1O_2) to electron-rich alkenes.^{87,88} Diastereoselective formation of dioxetanes has also been achieved by a chiral-auxiliary induced [2 + 2] cycloaddition of 1O_2 with a chiral allylic alcohol and enecarbamates.^{89–93} If alkenes are too electron-poor to react with 1O_2 , however, no oxygenated products were obtained. For example, no products were formed in an oxygen-saturated MeCN solution of TPE in the presence of 1O_2 sensitizers such as C_{60} or tetraphenylporphyrin under photoirradiation.⁴⁷ In contrast, the photocatalytic oxygenation of TPE by O_2 occurs efficiently with Acr^+-Mes via the radical ion coupling between TPE radical cation ($TPE^{+\bullet}$) and $O_2^{\bullet-}$, both of which are produced by electron-transfer reactions of TPE and O_2 with the photogenerated electron-transfer state of Acr^+-Mes ($Acr^+-Mes^{+\bullet}$),

leading to successful isolation of the corresponding 1,2-dioxetane.⁷⁹

Electron transfer from TPE to the $Mes^{+\bullet}$ moiety in $Acr^+-Mes^{+\bullet}$ is energetically feasible, because the one-electron reduction potential of $Acr^+-Mes^{+\bullet}$ in MeCN ($E_{red} = 1.88$ V vs SCE, saturated calomel electrode)⁴⁴ is more positive than the one-electron oxidation potential of TPE ($E_{ox} = 1.31$ V vs SCE in $CHCl_3$).⁷⁹ The second-order rate constant of electron transfer from TPE to $Acr^+-Mes^{+\bullet}$ was determined by laser flash photolysis measurements to be 2.5×10^9 $M^{-1} s^{-1}$ in $CHCl_3$, which is close to be the diffusion-limited value as expected from the exergonic electron transfer.⁷⁹ The second-order rate constant of the electron-transfer reduction of O_2 by the Acr^+ moiety was also determined to be 3.8×10^8 $M^{-1} s^{-1}$ in $CHCl_3$.⁷⁹ The formation of $O_2^{\bullet-}$ was confirmed by electron spin resonance (ESR), which was measured at 123 K immediately after the photoirradiation of a chloroform solution of TPE (1.0×10^{-3} M) and Acr^+-Mes (1.0×10^{-4} M) at 233 K.⁷⁹ The observed g values agree with those reported for $O_2^{\bullet-}$ ($g_{||} = 2.1050$ and $g_{\perp} = 2.0032$).^{94,95} The transient absorption band of $TPE^{+\bullet}$ decays second-order kinetics.⁷⁹ The second-order rate constant was determined to be 6.0×10^9 $M^{-1} s^{-1}$, which is close to the diffusion-limited value in $CHCl_3$.⁷⁹ The bimolecular process involves both the radical coupling between $TPE^{+\bullet}$ and $O_2^{\bullet-}$ to afford the corresponding dioxetane and the back electron transfer from $O_2^{\bullet-}$

Scheme 8 Photocatalytic oxygenation of TPE by O_2 with Acr^+-Mes .⁷⁹

to $TPE^{\bullet+}$ to regenerate the reactant pair as shown in Scheme 8.

The E_{ox} and E_{red} values of the dioxetane were determined by second-harmonic ac voltammetry as 1.56 V and -0.95 V versus SCE, respectively.⁷⁹ The E_{ox} value is less positive than the E_{red} value (1.88 V vs SCE in PhCN)⁴⁴ of the $Mes^{\bullet+}$ moiety of $Acr^+-Mes^{\bullet+}$, whereas the E_{ox} value of the $Acr^{\bullet}$ moiety (-0.57 V vs SCE) is less negative than the E_{red} value of the dioxetane. In such a case, the dioxetane is further oxidized by $Acr^+-Mes^{\bullet+}$ rather than by being reduced to produce the dioxetane radical cation, which undergoes the O–O bond homolysis to produce benzophenone and the radical cation as shown in Scheme 8.⁷⁹ The benzophenone radical cation is reduced by Acr^+-Mes to produce another benzophenone molecule, accompanied by regeneration of Acr^+-Mes (Scheme 8). The thermal oxygenation reaction of TPE with oxygen has previously been proposed to proceed via radical chain processes as shown in Scheme 9.^{96–98} The dioxetane is assumed to be produced by direct oxygenation of the dioxetane radical cation with O_2 . However, the saturated dependence of Φ on $[TPE]$ and also on $[O_2]$ indicates that such an electron-transfer radical chain process (Scheme 9) is not operative as the major pathway under the photocatalytic reaction conditions.⁷⁹

The formation of the dioxetane radical cation was confirmed by ESR measurements under photoirradiation at low temperature as shown in Figure 4.⁷⁹

Scheme 9 Radical chain process of photooxygenation of TPE via the dioxetane.

A deaerated chloroform solution of Acr^+-Mes with TPE dioxetane was irradiated by a high-pressure Hg lamp at 223 K. The resulting ESR spectrum observed at 143 K exhibits anisotropic signals at $g_{||} = 2.020$ and $g_{\perp} = 2.004$. The isotropic g value (g_{iso}) is determined as 2.009 ± 0.001 , which agrees with the reported value of a dioxetane radical cation (2.0099).⁹⁹ The formation of TPE dioxetane radical cation was also confirmed by photoinduced electron-transfer oxidation of TPE dioxetane with the singlet excited state of 9,10-dicyanoanthracene (DCA) ($^1E_{red}^* = 1.97$ V vs SCE) in frozen deaerated $CHCl_3$ at 143 K.⁷⁹ The resulting ESR signal was virtually the same as that shown in Figure 4a.⁷⁹ The singly occupied molecular orbital (SOMO) of dioxetane radical cation involves O–O antibonding orbital (Figure 4b).⁷⁹ This may be the reason why the facile cleavage of the O–O bond of the dioxetane radical cation occurs to yield benzophenone.¹⁰⁰

Figure 4 (a) ESR spectrum of TPE dioxetane radical cation observed under irradiation of a deaerated CHCl_3 solution containing TPE dioxetane (3.0×10^{-3} M) and Acr^+-Mes (3.7×10^{-2} M) at 223 K measured at 143 K (frozen). (b) The SOMO orbital of TPE dioxetane radical cation, calculated by DFT method using UB3LYP/6-31G* basis set.⁷⁹

Photocatalytic oxygenation of olefins such as stilbene derivatives also occurs with Acr^+-Mes in MeCN and CHCl_3 .¹⁰¹ In contrast to the case of TPE, the dioxetane intermediates were not detected under the same experimental conditions as employed for TPE.¹⁰¹ This indicates that the stilbene dioxetanes decompose to the corresponding benzaldehydes spontaneously under the photoirradiation. The yields of benzaldehyde derivatives obtained from *trans*-stilbene derivatives increase in order: $\text{R}^1, \text{R}^2 = \text{H}, \text{H} < \text{Me}, \text{Me} < p\text{-MeO}, \text{H}$, as the one-electron oxidation potential (E_{ox}) values of stilbene derivatives decrease.¹⁰¹ The photooxygenation mechanism of *cis*-stilbene catalyzed by Acr^+-Mes is shown in Scheme 10,¹⁰¹ which is similar to that of TPE (Scheme 8). Electron transfer from stilbene derivatives to the Mes^{++} moiety of $\text{Acr}^+-\text{Mes}^{++}$ is energetically feasible, because the E_{ox} values of stilbene derivatives (0.55–1.58 V vs SCE) are less positive than the E_{red} value of the Mes^{++} moiety of $\text{Acr}^+-\text{Mes}^{++}$ in PhCN (1.88 V vs SCE).⁴⁴ Because stilbene radical cation has low reactivity toward O_2 ,^{102–112} the photocatalytic oxygenation of stilbene with Acr^+-Mes occurs via the radical ion coupling between stilbene radical cation and $\text{O}_2^{\cdot-}$ rather than via the reaction of stilbene radical cation with O_2 , accompanied by the isomerization of the stilbene radical cation.¹⁰¹ The stilbene radical cation reacts with $\text{O}_2^{\cdot-}$ to produce the dioxetane that decompose spontaneously to benzaldehyde and benzaldehyde radical cation by the electron-transfer oxidation with the Mes^{++} moiety of $\text{Acr}^+-\text{Mes}^{++}$. The back electron transfer from Acr^+-Mes to benzaldehyde radical

cation yields benzaldehyde to regenerate Acr^+-Mes (Scheme 10).

Photocatalytic isomerization of *cis*-stilbene to *trans*-stilbene also occurs with Acr^+-Mes in an O_2 -saturated MeCN as shown in Scheme 10.¹⁰¹ The concentration of *cis*-stilbene decreases with a concomitant increase due to *trans*-stilbene, when the total concentration of *cis*- and *trans*-stilbene only slightly decreases together with an accompanied increase in the photooxygenation product, benzaldehyde.¹⁰¹ The observed yield of *trans*-stilbene was 96% after 60-min photoirradiation ($\lambda > 430$ nm), when the total consumption of *cis*- and *trans*-stilbene is still 4%.¹⁰¹ It is well known that *cis*-*trans* isomerization occurs rapidly in the stilbene radical cation.^{113–116} The steady-state *cis*-*trans* ratio of stilbene has been reported to be 99:1.¹¹⁶ Thus, Acr^+-Mes acts as a photocatalyst for the *cis*-*trans* isomerization of stilbene via the radical cation (Scheme 10).

3.3 Photocatalytic Oxygenation of *p*-Xylene and Reduction of Oxygen

As described above, photocatalytic oxygenation of aromatic substrates occurs via radical ion coupling of the substrate radical cation and $\text{O}_2^{\cdot-}$. This section describes photocatalytic oxygenation via the electron-transfer state of Acr^+-Mes without radical coupling. Oxygenation of aromatic compounds to produce aromatic aldehydes is key chemical reactions for production of precursors of a variety of

Scheme 10 Photocatalytic isomerization and oxygenation of stilbene by O_2 with Acr^+-Mes .¹⁰¹

fine or specialty chemicals such as pharmaceutical drugs, dyestuffs, pesticides, and perfume compositions. A number of methods using inorganic heavy metal oxidants have so far been reported for oxygenation of aromatic compounds to produce the corresponding aldehydes.^{117–122} However, their synthetic utility has been limited because of low yield and poor selectivity. Moreover, the use of stoichiometric amounts of inorganic oxidants should be avoided because of the environmental problems.¹²³ For this reason, catalytic oxygenation processes with molecular oxygen or hydrogen peroxide (H_2O_2) have merited increasing attention.¹²⁴ H_2O_2 is in brisk demands for clean and mild oxidant because the byproduct in oxygenation of substrates is only H_2O .^{124,125} There have been extensive studies on photocatalytic formation of H_2O_2 ^{126,127} or photocatalytic oxygenation of aromatic substrates.^{128–133} If valuable aromatic aldehydes can be produced together with H_2O_2 in the photocatalytic oxygenation of alkyl aromatic compounds by O_2 , such a process would be superior as compared to the conventional methods to produce either or both H_2O_2 and aromatic aldehydes.

Such selective photocatalytic oxygenation has been made possible using Acr^+-Mes and its derivative, which act as efficient photocatalysts for simultaneous production of aromatic aldehydes and H_2O_2 in the photocatalytic oxygenation of alkyl aromatic compounds by O_2 under

visible light irradiation.¹³⁴ Visible light irradiation of $[\text{Acr}^+-\text{Mes}]\text{ClO}_4^-$ ($\lambda_{\text{max}} = 430 \text{ nm}$, 0.20 mM) in oxygen-saturated MeCN containing *p*-xylene (4.0 mM) with a xenon lamp attached with a color glass filter ($\lambda = 380\text{--}500 \text{ nm}$) for 80 min resulted in formation of an oxygenated product, *p*-tolualdehyde (34%), *p*-methylbenzyl alcohol (10%), and H_2O_2 (30%). The overall stoichiometry of the photocatalytic reaction is given by (7).¹³⁴ *p*-Methylbenzyl alcohol is an intermediate in the photocatalytic oxygenation (*vide infra*):

The photocatalytic reactivity was enhanced by the presence of H_2O (0.9 M) and sulfuric acid (1.0 mM) to yield *p*-tolualdehyde (75%), *p*-methylbenzyl alcohol (15%), and H_2O_2 (74%) with a high quantum yield (0.25).¹³⁴ The 100% yields of *p*-tolualdehyde and H_2O_2 with a higher quantum yield (0.37) were achieved using 9-mesityl-2,7,10-trimethylacridinium ion ($\text{Me}_2\text{Acr}^+-\text{Mes}$), where the hydrogens at 2 and 7 positions of the acridinium ring are replaced by the methyl groups (Table 1).¹³⁴

Table 1 Products and quantum yields for photocatalytic oxygenation of methyl-substituted benzenes with acridinium ion derivatives in O₂-saturated MeCN.¹³⁴

Photocatalyst	Substrate	E_{ox} vs SCE (V) ^a	Yield (%) ^b aldehyde/alcohol/H ₂ O ₂	Quantum yield ^{b,c}
Acr ⁺ –Mes	<i>p</i> -Xylene	1.93	75/15/74 (34/3/30)	0.25 (0.13)

	Mesitylene	1.71	66/2/65 (40/1/39)	0.26 (0.14)
	Durene	1.63	64/10/62 (37/2/36)	0.25 (0.15)
Acr ⁺ –Ph	<i>p</i> -Xylene	1.93	12/18/10 (5/2/4)	0.042 (0.019)

^aTaken from Ref. 42.^bValues are determined after photoirradiation for 80 min. Conditions: [photocatalyst] = 0.2 mM, [substrate] = 4.0 mM, [H₂O] = 0.9 M, [H₂SO₄] = 1.0 mM. Values in parentheses are determined without H₂O and H₂SO₄.^cOn the basis of formation of the corresponding aldehyde.

No further oxygenated product, *p*-toluic acid or *p*-phthalaldehyde, was produced during the photocatalytic reaction. When the concentration of Me₂Acr⁺–Mes (1.0×10^{-4} M) was decreased, turnover number (TON) was increased to 200. A preparative scale photocatalytic reaction with *p*-xylene (0.5 g, 4.7 mmol) and Me₂Acr⁺–Mes (60 mg, 0.14 mmol) in MeCN (150 ml) under irradiation with a xenon lamp for 48 h afforded *p*-tolualdehyde (59%), *p*-methylbenzyl alcohol (28%), and H₂O₂ (51%) with 87% conversion of substrate.¹³⁴ The catalyst can be recyclable because no decomposition of photocatalyst occurred under the present experimental conditions.¹³⁴ Figure 5 shows the time profiles of the reactant and products in optimized photocatalytic reaction conditions. *p*-Methylbenzyl alcohol was formed as a reaction intermediate and this was readily oxygenated to form *p*-methylbenzaldehyde.¹³⁴

The photocatalytic oxygenation also occurred in the case of durene and mesitylene.¹³⁴ The one-electron oxidation potentials (E_{ox}) of toluene derivatives in MeCN are listed in Table 1. The E_{ox} values of toluene derivatives given in Table 1 are lower than the one-electron reduction potential (E_{red}) of the electron-transfer state of Acr⁺–Mes (Acr^{•+}–Mes^{•+}: 2.06 V vs SCE in MeCN).¹³⁴ Thus, electron transfer from toluene derivatives such as *p*-xylene to the Mes^{•+} moiety of Acr^{•+}–Mes^{•+} is energetically feasible, whereas electron transfer from toluene ($E_{\text{ox}} = 2.20$ V)^{42,134} to the Mes^{•+} moiety is energetically unfavorable when no photocatalytic oxidation of toluene by O₂ occurred with Acr⁺–Mes under the same experimental conditions.¹³⁴

**Figure 5** Irradiation time profiles of photooxygenation of *p*-xylene (4.0×10^{-3} M) catalyzed by Me₂Acr⁺–Mes in oxygen-saturated MeCN (0.6 ml) at 298 K; [Me₂Acr⁺–Mes] = 2.0×10^{-4} M; [H₂O] = 0.9 M; [H₂SO₄] = 1.0×10^{-3} M.¹³⁴

The E_{ox} values of the oxygenated products of the corresponding benzaldehydes are also higher than the E_{red} value of Acr^{•+}–Mes^{•+} (2.06 V).¹³⁴ This is the reason why the oxygenated product of *p*-xylene was only *p*-tolualdehyde and no further oxygenated product such as *p*-phthalaldehyde was formed.

The photocatalytic reaction is initiated by intramolecular photoinduced electron transfer from the mesitylene moiety to the singlet excited state of the Acr⁺ moiety of Acr⁺–Mes, which affords the electron-transfer state (Acr^{•+}–Mes^{•+}).^{44,134} Electron transfer from *p*-xylene to the Mes^{•+}

Scheme 11 Photocatalytic oxygenation of *p*-xylene by O_2 with Acr^+-Mes .¹³⁴

moiety occurs to produce *p*-xylene radical cation, which undergoes deprotonation to afford the deprotonated radical. This is followed by rapid O_2 addition to afford the peroxy radical as shown in Scheme 11.¹³⁴ The disproportionation of the peroxy radical affords *p*-tolualdehyde, *p*-methylbenzyl alcohol, and O_2 . *p*-Methylbenzyl alcohol is readily oxygenated to yield *p*-tolualdehyde with Acr^+-Mes .¹³⁴ On the other hand, $O_2^{\bullet-}$ disproportionates with proton to yield H_2O_2 and O_2 (Scheme 11). The radical intermediates involved in Scheme 11 were detected by ESR ($g_{||} = 2.101$, $g_{\perp} = 2.009$ for $O_2^{\bullet-}$ and $g_{||} = 2.033$, $g_{\perp} = 2.006$ for *p*-methylbenzyl peroxy radical) in frozen MeCN.¹³⁴

Addition of aqueous sulfuric acid enhanced the deprotonation of *p*-xylene radical cation and the disproportionation process of $O_2^{\bullet-}$, respectively, leading to a remarkable enhancement of photocatalytic reactivity as mentioned above (Table 1).¹³⁴ The reaction pathway of photocatalytic oxygenation of *p*-xylene by O_2 with Acr^+-Mes is not the radical chain process, because there was no dependence of the product quantum yield on concentration

Figure 6 Dependence of quantum yield of formation of *p*-tolualdehyde on concentration of *p*-xylene in the photocatalytic oxygenation of *p*-xylene with Me_2Acr^+-Mes (0.2 mM) in O_2 -saturated MeCN.¹³⁴

of *p*-xylene (Figure 6) and irradiation light intensity.¹³⁴ If the radical chain (autoxidation) process is

involved in the photocatalytic reaction, the quantum yield would increase linearly with increasing concentration of *p*-xylene, because the rate-determining step in the radical chain process would be the hydrogen abstraction from *p*-xylene by the peroxy radical. In addition, there is no induction period that is typically observed for an autoxidation process. Thus, disproportionation of the peroxy radicals (*p*-methylbenzyl peroxy radical and hydrogen peroxy radical as shown in Scheme 11) is the major pathway in the photocatalytic oxygenation of *p*-xylene by O₂ with Acr⁺–Mes.

In contrast to the case of Acr⁺–Mes, the photocatalytic oxygenation of *p*-xylene by O₂ with Acr⁺–Ph that contains no electron donor moiety proceeds via electron transfer from *p*-xylene to the singlet excited state of Acr⁺–Ph. However, the lifetime of the singlet excited state of Acr⁺–Ph ($\tau = 1.5$ ns in MeCN)¹³³ is much shorter than that of the electron-transfer state of Acr⁺–Mes. A high concentration of substrate is thereby needed to quench the short-lived singlet excited state of Acr⁺–Ph.

2-Methylnaphthalene that does not react with singlet oxygen (i.e., no conversion under irradiation conditions in the presence of tetraphenylporphyrin as a singlet oxygen photosensitizer) is also efficiently oxygenated by O₂ with Acr⁺–Mes acting as a photocatalyst to yield the corresponding naphthaldehyde.^{135,136} DCA also acts as a photocatalyst for the oxygenation of 2-methylnaphthalene by O₂ as a result of the photoinduced oxidation of 2-methylnaphthalene, followed by deprotonation from the methyl group, and O₂ addition,¹³⁵ which is similar to photocatalytic oxygenation of *p*-xylene by O₂ with Acr⁺–Mes as shown in Scheme 11.

The reducing ability of the electron-transfer state of Acr⁺–Mes is improved by the electron-donating methyl substitution of the acridinium ring of Acr⁺–Mes.¹³⁴ Cyclic voltammograms of Acr⁺–Mes and Me₂Acr⁺–Mes in deaerated MeCN are shown in Figure 7 to compare the reducing abilities of the electron-transfer states of Acr⁺–Mes and Me₂Acr⁺–Mes.¹³⁴ The E_{red} value of Me₂Acr⁺–Mes (–0.67 V vs SCE) is 0.1 eV more negative than that of Acr⁺–Mes (–0.57 V).¹³⁴

The difference in dynamics of the electron-transfer reduction of O₂ by the electron-transfer states of Acr⁺–Mes and Me₂Acr⁺–Mes was determined by nanosecond laser flash photolysis.¹³⁴ As shown in Figure 8a, the rates of the electron-transfer reduction were determined

Figure 7 Cyclic voltammograms of (a) Acr⁺–Mes and (b) Me₂Acr⁺–Mes (10 mM) in deaerated MeCN containing TBAPF₆ (0.1 M) at 298 K.¹³⁴

from the quenching of the transient absorption due to the electron-transfer state by O₂ to be $6.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for Acr⁺–Mes^{•+}⁷⁸ and $2.0 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ for Me₂Acr⁺–Mes^{•+} (Figure 8b).¹³⁴ Thus, the reducing ability of Me₂Acr⁺–Mes^{•+} was indeed significantly enhanced by the methyl substitution. This may be the reason why the 100% yield of tolualdehyde and H₂O₂ with a higher quantum yield (0.37) was achieved using Me₂Acr⁺–Mes (Table 1).

As described above, the electron-transfer state of Me₂Acr⁺–Mes, which has both the high oxidizing and reducing ability, make it possible to produce both aromatic aldehydes and H₂O₂ selectively in the photocatalytic oxygenation of alkylaromatic compounds with oxygen. After aromatic aldehydes are formed, no further oxidation takes place because electron transfer from aromatic aldehydes to the Mes^{•+} moiety is thermodynamically unfavorable. Thus, the use of charge-separation dyads as photocatalysts paves a new way for the selective oxygenation of alkylaromatic compounds with simultaneous formation of H₂O₂.

3.4 Photocatalytic Oxygenation of Triphenylphosphine

The photocatalytic oxygenation of triphenylphosphine by O₂ also occurs with Acr⁺–Mes.¹³⁷

Visible light irradiation ($\lambda > 430 \text{ nm}$) of the absorption band of Acr⁺–Mes in an O₂-saturated chloroform (CHCl₃) solution containing triphenylphosphine (Ph₃P) for 30 min by xenon lamp

Figure 8 (a) Absorbance time profiles at 520 nm due to $\text{Me}_2\text{Acr}^+-\text{Mes}^{*+}$ in aerated and deaerated MeCN containing $\text{Me}_2\text{Acr}^+-\text{Mes}$ ($1.0 \times 10^{-4} \text{ M}$). (b) Plot of the pseudo-first-order rate constant (k_{obs}) for electron transfer from the Acr^+ moiety of $\text{Acr}^+-\text{Mes}^{*+}$ and $\text{Me}_2\text{Acr}^+-\text{Mes}^{*+}$ to O_2 versus $[\text{O}_2]$.

results in formation of an oxygenated product, that is, triphenylphosphine oxide ($\text{Ph}_3\text{P}=\text{O}$) with 99% yield¹³⁷:

When Acr^+-Mes is replaced by 10-methyl-acridinium ion (AcrH^+) which has no electron donor moiety, $\text{Ph}_3\text{P}=\text{O}$ was also produced quantitatively after 60-min photoirradiation.¹³⁷ No photooxygenation of Ph_3P occurs without Acr^+-Mes or AcrH^+ under otherwise the same experimental conditions.¹³⁷ The dependence of the quantum yields (Φ_P) of formation of $\text{Ph}_3\text{P}=\text{O}$ on concentration of Ph_3P is shown in Figure 9 (closed circle).¹³⁷ The limiting value (Φ_∞) in air-saturated CHCl_3 is constant (0.58) at any Ph_3P concentrations. Judging from the constant dependence of Φ_P on $[\text{Ph}_3\text{P}]$ in Figure 9 (closed circle), a reactive intermediate of photooxygenation is assigned as an extremely long-lived species, which is the electron-transfer state of Acr^+-Mes .⁴⁴ Thus, the rate-determining step in the photocatalytic reaction is proposed to be electron transfer from Ph_3P to $\text{Acr}^+-\text{Mes}^{*+}$.¹³⁷

In the case of AcrH^+ (closed square in Figure 9), the Φ_P values increase on increasing the Ph_3P to higher concentrations than in the case of Acr^+-Mes . From the saturated dependence of Φ_P on $[\text{Ph}_3\text{P}]$ and the lifetime of $^1\text{AcrH}^{*+}$ ($\tau = 31 \text{ ns}$),^{131–133} the

Figure 9 Dependence of quantum yield (Φ_P) on concentrations of Ph_3P for the photocatalytic oxygenation of Ph_3P by O_2 with Acr^+-Mes ($8.0 \times 10^{-5} \text{ M}$, ●) and AcrH^+ ($8.0 \times 10^{-5} \text{ M}$, ■) in air-saturated CHCl_3 .

rate constant of the reaction of $^1\text{AcrH}^{*+}$ with Ph_3P is $6.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, which agrees with the value obtained from the fluorescence quenching of AcrH^+ ($9.0 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$).¹³⁷ Such agreement strongly indicates that the photooxygenation of Ph_3P with AcrH^+ proceeds via photoinduced electron transfer

from Ph_3P to $^1\text{AcrH}^{+*}$. However, AcrH^{+} -catalyzed photooxygenation requires the high concentrations of Ph_3P and O_2 because the lifetime of $^1\text{AcrH}^{+*}$ is too short to quench the excited state.¹³⁷

Electron transfer from Ph_3P to the Mes^{++} moiety in $\text{Acr}^+-\text{Mes}^{++}$ is energetically feasible, because the one-electron reduction potential of $\text{Acr}^+-\text{Mes}^{++}$ ($E_{\text{red}} = 2.06 \text{ V vs SCE}$)¹³⁴ is more positive than the one-electron oxidation potential of Ph_3P ($E_{\text{ox}} = 1.20 \text{ V vs SCE}$).¹³⁷ The formation of Ph_3P radical cation (Ph_3P^{+*} ; $\lambda_{\text{max}} = 330 \text{ nm}$)¹³⁷ was confirmed by the laser flash photolysis.¹³⁷ The second-order rate constant of electron transfer from Ph_3P to the Mes^{++} moiety of $\text{Acr}^+-\text{Mes}^{++}$ was determined to be $9.2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$,¹³⁷ which is close to the diffusion-limited value as expected from the exergonic electron transfer. Photoinduced electron transfer from Ph_3P to $^1\text{AcrH}^{+*}$ also occurs to yield Ph_3P^{+*} , which reacts with O_2 . The rate constant of the reaction of Ph_3P^{+*} with O_2 was determined to be $1.5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$.¹³⁸

The mechanism of the photocatalytic oxygenation of Ph_3P by O_2 with Acr^+-Mes is shown in Scheme 12. Triphenylphosphine peroxide (Ph_3PO_2) is produced via addition of O_2 to Ph_3P^{+*} to give Ph_3P peroxide radical cation ($\text{Ph}_3\text{PO}_2^{+*}$), which undergoes back electron transfer from Acr^+-Mes to $\text{Ph}_3\text{PO}_2^{+*}$ (reaction pathway A in Scheme 12) and via radical coupling between Ph_3P^{+*} and $\text{O}_2^{\cdot-}$ (reaction pathway B in Scheme 12). Ph_3PO_2 reacts with Ph_3P to produce $\text{Ph}_3\text{P}=\text{O}$ via O–O bond cleavage.^{139,140}

Scheme 12 Photocatalytic oxygenation of Ph_3P by O_2 with Acr^+-Mes .¹³⁷

3.5 Photocatalytic Oxidation of Benzylamine

Benzylamine is also oxidized by the photogenerated electron-transfer state of Acr^+-Mes in O_2 -saturated MeCN to yield *N*-benzylidenebenzylamine, $\text{PhCH}_2\text{N}=\text{CHPh}$.¹³⁷ The reaction mechanism of the photocatalytic oxidation of benzylamine by O_2 with Acr^+-Mes is shown in Scheme 13.¹³⁷ The photogenerated electron-transfer state of Acr^+-Mes ($\text{Acr}^+-\text{Mes}^{+*}$) oxidizes benzylamine and reduces O_2 by electron transfer to produce the benzylamine radical cation and $\text{O}_2^{\cdot-}$, respectively. The subsequent proton transfer occurs from benzylamine radical cation to $\text{O}_2^{\cdot-}$ to give the α -hydrogen abstracted radical of benzylamine and hydrogen peroxyl radical ($\text{HO}_2^{\cdot}$). The α -hydrogen abstracted radical spontaneously reacts with $\text{HO}_2^{\cdot}$ to form benzylimine ($\text{PhCH}=\text{NH}$) and hydrogen peroxide (H_2O_2). $\text{PhCH}=\text{NH}$ reacts with benzylamine to produce the primary product $\text{PhCH}_2\text{N}=\text{CHPh}$ (Scheme 13).^{141–143}

3.6 Photocatalytic Oxidation and Cleavage of DNA

Photoinduced DNA cleavage has attracted considerable interest because of the biological significance of DNA damage and repair (see **Oxidatively Generated Nucleobase Modifications in Isolated and Cellular DNA and Oxidatively Formed Sugar Radicals in Nucleic Acids**).^{144–149}

Scheme 13 Photocatalytic oxidation of benzylamine by O₂ with Acr⁺-Mes.¹³⁷

The DNA cleavage resulted from efficient electron-transfer oxidation by the electron-transfer state of Acr⁺-Mes.^{150,151} The reduction potential of Acr^{*}-Mes^{•+} ($E_{\text{red}} = 2.06 \text{ V}$ vs SCE in MeCN)¹³⁴ is much more positive than the one-electron oxidation potential of guanosine-5'-monophosphate (GMP, $E_{\text{ox}} = 1.07 \text{ V}$ vs SCE in an aqueous solution).¹⁵² Thus, electron transfer from GMP to the Mes^{•+} moiety of Acr^{*}-Mes^{•+} is energetically feasible.¹⁵⁰ Formation of GMP radical cation (GMP^{•+}; $\lambda_{\text{max}} = 510 \text{ nm}$) is observed by the laser photoirradiation of a buffer solution of Acr⁺-Mes at pH 2.0 containing GMP as shown in Figure 10a (closed rectangles).¹⁵⁰ At pH 7.0, a transient absorption at the long wavelength region circa at 650 nm appears because of the deprotonation of GMP^{•+} (closed circles in Figure 10a).^{153,154} The difference spectra given in Figure 10b, obtained by subtracting the spectra in the absence of GMP from those in the presence of GMP at pH 2.0 and 7.0, correspond to those between GMP^{•+} (positive absorption) and the Mes^{•+} moiety (negative absorption), because the spectra in the absence and the presence of GMP are those of Acr^{*}-Mes^{•+} and those of GMP^{•+} and Acr^{*}-Mes, respectively.¹⁵⁰ The rate of formation of GMP^{•+} obeyed pseudo-first-order kinetics and the pseudo-first-order rate constant increased linearly with increasing concentration of GMP at pH 2.0.¹⁵⁰ The second-order rate constant (k_{et}) of electron transfer from GMP to the Mes^{•+} moiety of Acr^{*}-Mes^{•+} was determined to be $4.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ in the buffer solution at 298 K.¹⁵⁰ The k_{et} value of electron transfer from GMP to the Mes^{•+} moiety of Acr^{*}-Mes^{•+} was also determined to be $2.7 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ at pH 7.0, which is much larger than the value ($4.3 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) at pH 2.0, but

still smaller than the diffusion limit.¹⁵⁰ The larger k_{et} value at the higher pH indicates the involvement of deprotonation associated with electron transfer (proton-coupled electron transfer).^{155,156}

The transient absorption spectrum of oxidized DNA shown in Figure 11 is similar to that of GMP^{•+} in Figure 10.¹⁵⁰ The k_{et} value of the electron-transfer oxidation of DNA was determined to be $4.8 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, which is larger than the k_{et} value of GMP.¹⁵⁰ The electron-transfer oxidation of DNA results in the cleavage of DNA.¹⁵⁰ The DNA cleavage activity with Acr⁺-Mes in the absence of O₂ was much higher than that in the presence of O₂ at pH 5.0 and 7.0.¹⁵⁰ This indicates that O₂ acts as an apparent inhibitor for the DNA cleavage. When DNA is oxidized by the Mes^{•+} moiety of Acr^{*}-Mes^{•+}, O₂ is reduced by the Acr^{*} moiety to produce O₂^{•-}.^{78,150} The retarding effect of O₂ may result from more efficient back electron transfer from O₂^{•-} to DNA radical cation as compared with that from the Acr^{*} moiety to DNA radical cation before oxidizing DNA as shown in Scheme 14.¹⁵⁰

Although all DNA bases can be oxidized by the Mes^{•+} moiety of Acr^{*}-Mes^{•+}, the largest k_{et} value of the electron-transfer oxidation of GMP together with the lowest oxidation potential of GMP among DNA bases indicate that guanine is eventually oxidized in electron transfer from DNA to the Mes^{•+} moiety of Acr^{*}-Mes^{•+}, leading to efficient DNA cleavage.¹⁵⁷ In the present case, however, no hydroxyl radical (HO^{*}) was formed because the photoexcitation of Acr⁺-Mes affords the electron-transfer state, which oxidizes DNA without involvement of the triplet excited state.¹⁵⁸ The higher DNA cleavage activity at pH 5.0 as compared with that at pH 7.0 suggests

Figure 10 (a) Transient absorption spectra of Acr^+-Mes in the presence and absence of GMP (1.0×10^{-2} M) at pH 2.0 and 7.0; (b) difference transient absorption spectra of GMP^{++} (pH 2.0) and $(\text{GMP}-\text{H})^+$ (pH 7.0), obtained by subtracting the spectra in the absence of GMP from those in the presence of GMP at pH 2.0 and 7.0, respectively.¹⁵⁰

Figure 11 Transient absorption spectrum of Acr^+-Mes (6.0×10^{-5} M) in the presence of calf thymus DNA (CT DNA) (1.0×10^{-3} M) and the difference spectrum of DNA radical cation at pH 7.0 measured at 250 μs after laser excitation at $\lambda = 355$ nm at 298 K.¹⁵⁰

Scheme 14 Photocatalytic oxidation and cleavage of DNA by O_2 with Acr^+-Mes .¹⁵⁰

that guanine radical cation has a higher reactivity for the DNA cleavage than the deprotonated radical (Scheme 14), judging from the pK_a value of guanine radical cation ($pK_a = 3.9$).¹⁵⁴

4 PHOTOCATALYTIC BROMINATION VIA CHARGE SEPARATION

Acr^+-Mes was found to act as an efficient photocatalyst for selective bromination of aromatic hydrocarbons and thiophenes with aqueous HBr as a Br source without using a toxic bromine source and O_2 as a green oxidant under visible light irradiation.¹⁵⁹ It should be noted that bromination of thiophenes is particularly important in the preparation of oligothiophenes and polythiophenes,^{160–174} which have many applications as conductive, semiconductive, nonlinear optical, and liquid crystalline materials.¹⁷⁵

Visible light irradiation of $[Acr^+-Mes]ClO_4^-$ ($\lambda_{max} = 430$ nm, 0.20 mM) in an oxygen-saturated MeCN solution containing 1,2,4-trimethoxybenzene (TMB, 4.0 mM), 50% aqueous HBr ($[HBr] = 20$ mM, $[H_2O] = 100$ mM) with a xenon lamp attached with UV-cut glass filter ($\lambda < 320$ nm) for 20 min resulted in formation of a brominated product, 2,4,5-trimethoxybromobenzene.¹⁵⁹ The overall stoichiometry of the photocatalytic reaction is given by

the following equation:

The yield and selectivity of 2,4,5-trimethoxybromo-benzene is nearly 100%, because no further brominated product, dibromo- or tribromo-derivative, was produced in these reaction conditions.¹⁵⁹ The products and quantum yields are listed in Table 2.¹⁵⁹ Photocatalytic bromination reactions of various aromatic compounds also occurred as shown in Table 2. A preparative scale

Table 2 Product and quantum yields for photocatalytic bromination of organic compounds by O₂ and HBr with Acr⁺–Mes in MeCN, and one-electron oxidation potentials of substrates.¹⁵⁹

Entry	Substrate	Product	Conversion ^a (%)	Yield ^a (%)	Time (h)	Quantum yield ^a (%)	E _{ox} ^b (V)

9			>99	53	2	0.36	1.33
10			>99	44	2	0.32	1.47

^a Conditions: [substrate] = 4.0 mM; [Acr⁺–Mes] = 0.20 mM; [HBr] = 20 mM; [H₂O] = 100 mM.^b Values are determined by cyclic voltammetry and second harmonic ac voltammetry.^c Minor product is mainly the dibromo compound.

Figure 12 (a) Transient absorption spectra of the electron-transfer state of Acr⁺-Mes (0.2 mM) in the absence and presence of TMB (0.3 mM) in deaerated MeCN after nanosecond laser excitation at 430 nm. (b) Plot of k_{rise} versus [TMB] or [HBr] for the reaction of Acr⁺-Mes⁺ with TMB or HBr. (c) Plot of k_{decay} versus [HBr] for the reaction of TMB⁺ with HBr.¹⁵⁹

photocatalytic reaction of TMB (200 mg, 1.2 mmol) with 50% aqueous HBr (160 μ l 1.5 mmol) in the presence of Acr⁺-Mes (0.044 mmol) in an oxygen-saturated MeCN under photoirradiation by a xenon lamp for 24 h affords the brominated product in 100% selectivity and in 81% yield.¹⁵⁹

The photodynamics of the photocatalytic bromination of TMB with HBr in the presence of Acr⁺-Mes was revealed by nanosecond laser flash photolysis.¹⁵⁹ A transient absorption spectrum due to the electron-transfer state of Acr⁺-Mes (Acr⁺-Mes⁺) is observed after the laser pulse excitation at 430 nm of an MeCN solution of Acr⁺-Mes as shown in Figure 12 (blue line).¹⁵⁹ The broad absorption band in the NIR region is attributed to the π -dimer of Acr⁺-Mes⁺ with the ground state of Acr⁺-Mes as described earlier.⁵⁵ In the presence of TMB, a new band at 450 nm appeared at 12 μ s as shown in Figure 12 (red line), which is assigned to TMB radical cation (TMB⁺).¹⁵⁹ The rate constant for electron transfer from TMB to the

Mes⁺ at the electron-transfer state of Acr⁺-Mes was determined from the slope of the linear plot of k_{rise} versus [TMB] to be $k_{\text{TMB}} = 2.0 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ (Figure 12b).¹⁵⁹ The rate of disappearance of TMB⁺ was accelerated by increasing the concentration of HBr.¹⁵⁹ The observed decay rate constant (k_{decay}) increases linearly with increasing concentrations of HBr as shown in Figure 12c.¹⁵⁹ Thus, TMB⁺ efficiently reacts with Br⁻ to form the Br adduct radical [TMB(Br)[•]]. The rate constant of the addition of Br⁻ was determined from the slope of k_{decay} versus [HBr] to be $k_{\text{HBr}} = 1.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ (Figure 12c).¹⁵⁹ The electron-transfer oxidation of Br⁻ in the photocatalytic reaction was also revealed by quenching of Acr⁺-Mes⁺ by HBr. The quenching rate constant of Acr⁺-Mes⁺ with HBr is two orders of magnitude smaller ($2.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) than the k_{TMB} value (Figure 12b).¹⁵⁹ Thus, the electron-transfer oxidation of hexamethylbenzene (HMB) predominated over the oxidation of Br⁻.

The one-electron oxidation potentials (E_{ox}) of aromatic compounds in deaerated MeCN (0.96–1.76 V) listed in Table 2 are lower than the one-electron reduction potential of the electron-transfer state of Acr^+-Mes ($\text{Acr}^{\bullet}-\text{Mes}^{++}$; $E_{\text{red}} = 2.06 \text{ V}$ vs SCE).^{134,159} Thus, electron transfer from aromatic compounds such as TMB to $\text{Acr}^{\bullet}-\text{Mes}^{++}$ is energetically favorable, whereas electron transfer from toluene ($E_{\text{ox}} = 2.20 \text{ V}$) and benzene (2.32 V) to the Mes^{++} moiety of $\text{Acr}^{\bullet}-\text{Mes}^{++}$ is energetically unfavorable. In such a case, no photocatalytic bromination of benzene or toluene occurs under the same experimental conditions as TMB. The decreased reactivity of methoxybenzene (entry 7 in Table 2) is attributed to the high E_{ox} value (1.76 V). On the other hand, the one-electron reduction of O_2 by the electron-transfer state of Acr^+-Mes in the presence of an acid is known to occur efficiently, producing $\text{HO}_2^{\bullet}$ that disproportionates to yield H_2O_2 and O_2 .¹⁷⁶ The rate constant of electron-transfer reduction of O_2 (k_{O_2}) was reported to be $6.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$.¹³⁴

The photocatalytic bromination of TMB by HBr with Acr^+-Mes is initiated by intramolecular photoinduced electron transfer from the Mes moiety to the singlet excited state of the Acr^+ moiety of Acr^+-Mes to generate $\text{Acr}^{\bullet}-\text{Mes}^{++}$ as shown in Scheme 15.^{44,159}

The Mes^{++} moiety of $\text{Acr}^{\bullet}-\text{Mes}^{++}$ can oxidize TMB to produce TMB^{++} , whereas the $\text{Acr}^{\bullet}$ moiety can reduce O_2 to $\text{HO}_2^{\bullet}$.¹⁵⁹ The TMB^{++} thus produced reacts with Br^- to form the Br adduct radical, which undergoes dehydrogenation with protonated $\text{HO}_2^{\bullet}$ to afford the corresponding brominated product and hydrogen peroxide.¹⁵⁹ Hydrogen peroxide further reacts with HBr and substrate to

produce another brominated product and H_2O .¹⁷⁷ The quantum yield remained constant on increasing the concentration of TMB and the light intensity under the present experimental conditions.¹⁵⁹ This suggests that no radical chain process is involved in the present photocatalytic aerobic bromination of substrates with HBr.

5 CARBON–CARBON BOND FORMATION VIA CHARGE SEPARATION

5.1 Oligomerization of Fullerene

Because the photogenerated electron-transfer state of Acr^+-Mes ($\text{Acr}^{\bullet}-\text{Mes}^{++}$) has both the highly oxidizing and reducing ability, the same substrate (S) can be oxidized and reduced by $\text{Acr}^{\bullet}-\text{Mes}^{++}$ to produce the radical cation ($\text{S}^{+\bullet}$) and the radical anion ($\text{S}^{-\bullet}$), which can be coupled to yield the dimer ($\text{S}-\text{S}$). Such an example has been reported for the coupling of fullerene radical cation ($\text{C}_{60}^{+\bullet}$) and fullerene radical anion ($\text{C}_{60}^{-\bullet}$), which are produced by electron-transfer oxidation and reduction of C_{60} with $\text{Acr}^{\bullet}-\text{Mes}^{++}$ as shown in Scheme 16.¹⁷⁸ The coupling products were fullerene oligomers, C_{120} , C_{180} , and C_{240} .¹⁷⁸

Nanosecond laser excitation at 430 nm of a deaerated PhCN solution containing Acr^+-Mes and C_{60} results in the appearance of new transient absorption bands in the NIR region, which are the superposition of those due to $\text{C}_{60}^{+\bullet}$ (960 nm) and $\text{C}_{60}^{-\bullet}$ (1080 nm) as shown in Figure 13a.^{178–180} The transient absorption bands of $\text{C}_{60}^{+\bullet}$ and $\text{C}_{60}^{-\bullet}$ disappear, accompanied by appearance of a new absorption band at 740 nm due to the triplet excited

Scheme 15 Photocatalytic bromination of alkylbenzenes by HBr and O_2 with Acr^+-Mes .¹⁵⁹

Scheme 16 Photocatalytic oligomerization of fullerene with Acr^+-Mes .¹⁷⁸

Figure 13 (a) Transient absorption spectra in PhCN observed in photoinduced electron-transfer oxidation of C_{60} (1.0×10^{-4} M) with $\text{Acr}^+-\text{MesClO}_4^-$ (1.0×10^{-4} M) taken 1.0 and 4.0 μs after laser excitation at 430 nm at 298 K. (b) Time profiles at 740, 960, and 1080 nm in PhCN.¹⁷⁸

state of C_{60} ($^3\text{C}_{60}^*$) (Figure 13b). The reaction mechanism of photoinduced oligomerization of C_{60} with Acr^+-Mes is summarized in Scheme 16, where only a linear isomer is shown for C_{180} .¹⁷⁸

Because the free energy change of electron transfer (ΔG_{et}) from C_{60} ($E_{\text{ox}} = 1.73$ V vs SCE)^{180,181} to the Mes^+ moiety of the electron-transfer state of Acr^+-Mes in PhCN ($E_{\text{ox}} = 1.88$ V)^{44,78} is negative

($\Delta G_{\text{et}} = -0.15$ eV), the electron-transfer oxidation C_{60} is energetically feasible to form $\text{C}_{60}^{\bullet+}$. On the other hand, the electron-transfer reduction of C_{60} ($E_{\text{red}} = -0.43$ V)¹⁸² with the $\text{Acr}^{\bullet}$ moiety ($E_{\text{red}} = -0.49$ V)^{44,78} is also thermodynamically feasible to give $\text{C}_{60}^{\bullet-}$ ($\Delta G_{\text{et}} = -0.06$ eV). Thus, C_{60} acts as both an electron donor and acceptor in electron-transfer reactions of $\text{Acr}^{\bullet}\text{-Mes}^+$ with C_{60} to produce $\text{C}_{60}^{\bullet+}$ and $\text{C}_{60}^{\bullet-}$ at the same time. The [2 + 2]cycloaddition occurs efficiently between $\text{C}_{60}^{\bullet+}$ and $\text{C}_{60}^{\bullet-}$ to afford ${}^3\text{C}_{120}^*$ rather than C_{120} , because the driving force of charge recombination (2.16 eV) is larger than the triplet excited state energy of C_{120} (circa 1.5 eV).^{178,183} The radical coupling between $\text{C}_{60}^{\bullet-}$ and $\text{C}_{60}^{\bullet+}$ also affords the triplet excited state of C_{60} (${}^3\text{C}_{60}^*$). Further oligomerization occurs by the same process.

Figure 14 Crystal structure of dimethylllepidoptere produced in the Acr^+-Mes -catalyzed photochemical reaction of DMA.¹⁸⁴

5.2 Photocatalytic Dimerization of Anthracene

Photodimerization of anthracene is made possible using Acr^+-Mes as a photocatalyst in CHCl_3 .¹⁸⁴ When the photochemical reaction of 9,10-dimethylantracene with Acr^+-Mes was carried out without O_2 in CHCl_3 , photocatalytic carbon-carbon bond formation occurred efficiently to give dimethylllepidoptere (5,6,11,12-tetrahydro-5,12-dimethyl-4*b*,12[1',2']: 6,10*b*[1'',2'']-dibenzo-chrysene).¹⁸⁴ The X-ray crystal structure of dimethylllepidoptere is shown in Figure 14.¹⁸⁴ In the crystal structure, the bond length of the newly formed C-C bond (C6-C6') is 1.629(2) Å, which is much longer than normal C-C single bonds, indicating severe distortion of this compound.¹⁸⁴ The synthesis of another type of anthracene dimer such as lepidoptere has previously been carried out by intramolecular Diels-Alder reaction of 9-anthrylmethyl *a,p*-dimer,¹⁸⁵⁻¹⁸⁹ dehalogenation of 9-chloromethylantracene,^{190,191} oxidation of 9-methylantracene with copper(II)/peroxy-disulfate,¹⁹² photolysis of 9-(*N,N*-dimethylamino)-anthracene,¹⁹³ 9-(phenoxymethyl)anthracene,¹⁹⁴ and 9-anthracenylmethylsulfides and selenides.¹⁹⁵

The one-pot synthesis of the lepidoptere from the corresponding anthracene has been made possible using Acr^+-Mes as a photocatalyst as shown in Scheme 17.¹⁸⁴ Photoirradiation of Acr^+-Mes

affords the electron-transfer state ($\text{Acr}^{\bullet}-\text{Mes}^+$), followed by electron transfer from DMA to $\text{Acr}^{\bullet}-\text{Mes}^+$ to produce $\text{DMA}^{\bullet+}$ and $\text{Acr}^{\bullet}-\text{Mes}$. The deprotonation from the methyl group of $\text{DMA}^{\bullet+}$ is the key step for the formation of dimethylllepidoptere as shown in Scheme 17. There are two ways of radical coupling of the deprotonated radicals to produce the dimers: lepidoptere and 1,2-bis(9-anthracenyl)ethane (Scheme 17). The $\text{Acr}^{\bullet}$ moiety of $\text{Acr}^{\bullet}-\text{Mes}$, produced by electron transfer from DMA to $\text{Acr}^+-\text{Mes}^+$, is oxidized by dissociative electron transfer to CHCl_3 to produce $\text{CHCl}_2^{\bullet}$ and Cl^- . The $\text{CHCl}_2^{\bullet}$ radicals dimerize to yield 1,1,2,2-tetrachloroethane ($\text{CHCl}_2\text{CHCl}_2$) as shown in Scheme 17.¹⁸⁴

The improvement of the dimer product yield can be achieved by the addition of a base such as tetrabutylammonium hydroxide (TBAOH), which accelerates deprotonation of $\text{DMA}^{\bullet+}$.¹⁸⁴ When TBAOH was introduced to a CHCl_3 solution containing DMA and Acr^+-Mes , the isolated yield of dimethylllepidoptere was increased to 21%, as compared with the yield in the absence of the base (12%).¹⁸⁴

6 SUMMARY

As described above, a variety of photocatalytic reactions are made possible using the electron-transfer state of Acr^+-Mes , which can oxidize and reduce

Scheme 17 Photocatalytic formation of dimethylepidoptere with Acr^+-Mes .¹⁸⁴

external electron donors and acceptors to produce the radical cations and anions, respectively. The reactions of radical cations with superoxide anion ($\text{O}_2^{\cdot-}$) can efficiently compete with the back electron transfer to yield the oxygenated products. Substrates that cannot react with singlet oxygen can be readily oxygenated by oxygen with Acr^+-Mes under visible light irradiation. The oxygenated products become much more difficult to be oxidized by the electron-transfer state of Acr^+-Mes , when the selective photocatalytic oxygenation of substrates, which would otherwise be very difficult to achieve, has been made possible with Acr^+-Mes . The reactions of radical cations produced by electron transfer from electron donor substrates to the electron-transfer state of Acr^+-Mes with nucleophiles such as Br^- can also afford the adducts with nucleophiles, when the electron-transfer oxidation of substrates with the electron-transfer state

of Acr^+-Mes is much faster than that of nucleophiles. In addition, the radical coupling of neutral radicals produced by deprotonation of the produced radical cations can be utilized for the C–C bond formation reactions. Thus, photocatalytic reactions of Acr^+-Mes under visible light irradiation provide new ways to design environmentally benign synthesis.

Conducting Polymers: Applications in Electronics and Photovoltaics

Huanli Dong and Wenping Hu

Beijing National Laboratory for Molecular Sciences, Key Laboratory of Organic Solids, Institute of Chemistry, Chinese Academy of Sciences, Beijing, People's Republic of China

1 INTRODUCTION

1.1 Prologue

The Nobel Prize for Chemistry in 2000 was awarded to Professors Alan Heeger, Alan MacDiarmid, and Hideki Shirakawa for their great discovery of conducting polymer that “doped” polyacetylene can conduct electricity, which immediately shocked the world and changed the initial way in which polymers were only viewed as insulators. Since then, significant academic and commercial interest in conjugated polymers was evoked for their wide region of physical properties from insulating, semiconducting to highly conducting (metallic) state through reasonable molecular tailoring^{1–4} and their superior solution-processed ability over the traditional inorganic materials for promising applications in the context of flexible, low-cost, and large-area optoelectronic devices.^{5–9} Till date, this field has evolved three typical generation processes from the early work on polyacetylene (the first generation) to a special focus on soluble and processable polymers (the second generation) and then to currently the more complex copolymer materials (the third generation),¹⁰ aiming to meet different application areas. Among them, polymer-based light-emitting diodes (PLEDs), polymer-based field-effect transistors (PFETs), and polymer-based solar cells (PSCs) are the most representative application fields for

conducting polymers and have received particular and extensive attention over the past decades. Encouragingly, till date, PLEDs are becoming commercially available, representing the final step in the advance of organic electronics from laboratory curiosity to a part of daily life. In contrast, PFETs and PSCs have been left behind. Nevertheless, the past success in PLEDs provides scientists enough confidence that in near future there will be vital alternatives of PFETs and PSCs in commercial world to their inorganic counterparts. Figure 1 shows the number of publications versus years for PFETs and PSCs obtained from the ISI web of knowledge, clearly indicating the increasing research interest in these fields.

In spite of current success for PLEDs in the market place, such as most notably the displays of several mobile electronic applications,^{8,9,11,12} the goal of this article will mainly focus on the important and updated development in fields of PFETs and PSCs, in order to give a concise review especially regarding those which play important role in leading the development trend in terms of both new materials and device applications, in order to provide a valuable guideline for driving their true commercialization. Before discussing these representative developments, it is quite necessary to give a basic introduction to PFETs and PSCs, including their device structures, principles of operation, as well as the research background and the state-of-the-art.

Figure 1 Number of literature publications versus years for (a) PFETs and (b) PSCs obtained from ISI web of knowledge searching with the keywords “polymer field-effect transistor(s)” and “polymer solar cells or polymer photovoltaics”, respectively.

1.2 Basic Knowledge of PFETs

An organic field-effect transistor (OFET) is a three-terminal device composed of a gate electrode, a gate insulator layer, a semiconducting layer, and the source/drain electrodes. According to the relative position of every component, field-effect transistor has four typical device structures (as shown in Figure 2a). In principle, bottom-gate top-contact (BGTC) is the most usually investigated device

structures for PFETs due to its intimate contact between the semiconducting layer and source/drain electrodes and thus resulting in low contact resistance and higher device performance. However, from the viewpoint of large-area applications, top-gate bottom-contact (TGBC) and bottom-gate bottom-contact (BGBC) are the ideal device structures because they can be easily manipulated with inexpensive fabrication techniques, such as gravure printing, flexographic, inkjet printing, and so on.

Figure 2 (a) The common structures of OFETs. Typical I - V characteristics of a pentacene-based BGTC p-channel OFET with gate dielectric of PS (15 nm)-modified 300 nm SiO_2 , (b) output, and (c) transfer curves. [Reproduced from Ref. 13. © Wiley-VCH Verlag GmbH & Co. KGaA, 2010.]

Simply speaking, OFETs can be seen as a capacitor between the gate electrode and semiconductor layer. Under applying a gate voltage, there are induced charges (holes for p-type or electrons for n-type) occurring in the semiconductor thin film near the insulator, and then these induced charges transport from the source electrode to the drain electrode by applying a certain source-drain voltage and produce current. Compared to that of no applied gate voltage, the channel current can be significantly increased by several orders, depending on the applied gate voltage. The performance of OFETs is usually characterized by parameters such as field-effect mobility ($\mu/(\text{cm}^2 \text{Vs}^{-1})$), on/off ratio ($I_{\text{on/off}}$), and threshold voltage (V_{th}/V), which can be calculated through the transfer and output curves (as shown in Figure 2b and c).

In the linear region, the μ value is given as following:

$$I_{\text{DS}} = \frac{W}{L} \mu C_i (V_{\text{GS}} - V_{\text{th}}) V_{\text{DS}} \quad (1)$$

While in the saturation region, the μ value is given as follows:

$$I_{\text{DS}} = \frac{W}{2L} \mu C_i (V_{\text{GS}} - V_{\text{th}})^2 \quad (2)$$

Beside this, the $I_{\text{on/off}}$ is the ratio of the highest current value/the lowest current value in the transfer curve, the V_{th} can be determined by extrapolating a plot of $(I_{\text{DS,sat}})^{1/2}$ versus V_{GS} to $I_{\text{DS}} = 0$. Field-effect mobility, as one of the most important parameters, refers to the absolute value of the ratio of the velocity to the electric field, which is affected by many factors, such as semiconductor materials, device fabrication process, interface properties as well as measurement conditions.^{14,15} Since the first report of PFETs (mobility was only $10^{-5} \text{ cm}^2 \text{Vs}^{-1}$),¹⁶ they have undergone remarkable progress and the highest field-effect mobility reported so far for PFETs has been up to $1.4 \text{ cm}^2 \text{Vs}^{-1}$,¹⁷ which has been comparable to amorphous silicon, indicating their tremendous potential for future applications.

1.3 Basic Knowledge of PSCs

Different from field-effect transistor, solar cell is a kind of device that operates in converting light into

electricity through the following steps: absorption of photons leading to the formation of excitons, that is, the bond electron-hole pairs; exciton diffusion for dissociation, that is, charge separation occurs; and then charges transport within organic semiconductor to electrodes and connect by electrodes to generate photocurrent and photovoltage. Under the consideration of energy sustainability and environmental protection, PSCs have received widespread attention as a source of clean and renewable energy particularly due to its potential for large-area and low-cost applications. The first PSC device was reported by Karg *et al.* 1993¹⁸ based on poly(*p*-phenylene-vinylene) with a single layer device structure, and only about 0.1% conversion efficiency was obtained for such solar cells. And then, in 1986, Tang *et al.*¹⁹ introduced the concept of two-layer device architecture into the organic solar cells, and much progress has been made for organic photovoltaic cells due to the incorporation of a donor-accept interface in the active layer, which generates the charge separation and produces higher photocurrent. However, the small interfacial areas and the limited thickness for exciton diffusion make it very difficult for the further enhancement of such two-layer device performance. To overcome these limitations, a concept of bulk heterojunction (BHJ) solar cells (as shown in Figure 3a) was proposed by Yu *et al.*²⁰ in 1995. By blending donor and acceptor materials together, an interpenetrating network with a large D–A interfacial area can be achieved through controlling the phase separation between the two components in bulk. In this way, any absorbing site in the composite is within a few nanometers to the donor–acceptor interface, leading to much enhanced quantum efficiency of charge separation. The formation of the continuous network creates two channels to transport holes in the donor domain and electrons in the acceptor domain, resulting in an efficient charge collection.²¹ So far, this structure strategy has become the research mainstream in PSCs and has obtained very good success. The device efficiency has been significantly improved from the initial report value of 0.1%¹⁸ to current value of approaching 8%,²² representing a breakthrough in the PSCs' performance and bringing a bright future for PSCs' future applications.

The performance of PSCs can be characterized by the following essential parameters, such as J_{sc} (the short-circuit current), V_{oc} (the open-circuit voltage), J_{mp} , and V_{mp} referring to the current and voltage,

Figure 3 (a) Architecture of a bulk heterojunction photovoltaic device using indium tin oxide (ITO) as the electrode and poly[3,4-(ethylenedioxy)thiophene] poly(styrenesulfonate) (PEDOT:PSS) as the hole-conducting layer. The enlarged area shows the active layer consisting of a conjugated polymer [6,6]-phenyl-C₆₁-butyric acid methyl ester (PCBM) composite with a bicontinuous interpenetrating morphology with domain sizes between 10 and 20 nm. (The bottom one is a TEM image, and the top one is a drawing illustration.) (b) Current voltage ($J-V$) characteristics and the corresponding power voltage curve for a BHJ solar cell under illumination. [Reprinted with permission from Ref. 21. Copyright 2009 American Chemical Society.]

respectively, at which a given device's electrical power output is the maximum, $P_{\max}$, the fill factor (FF) (a graphic measure of the square of the I - V curve), and the power conversion efficiency (PCE) (which is defined as the ratio of maximum power output ($P_{\max}$) to power input (P_{in})). They are usually obtained through the current-voltage (I - V) curves with corresponding equations shown in Figure 3b.

From the above brief introduction, we can see that the current breakthrough development has been made in both PFETs and PSCs, specifically in terms of field-effect mobility for PFETs and device efficiency for PSCs. However, to combine all these essential parameters for PFETs or PSCs into a useful technology, further research in device science and new materials is needed. As the core component of PFETs and PSCs, semiconducting layer plays the crucial role in determining the whole device performance. So, in the following sections, we will firstly give a relatively comprehensive summary on the recent important and representative progresses in both these two fields, with special emphasis on novel concepts of molecular designs, optimizing the device fabrication from a view point of materials, such as thermal annealing, interface modification as well as solvent effect, and so on, for the enhancement of device performance. Then, we will briefly introduce some of their prospective applications in flexible and large-area organic electronics. Finally, a conclusion and outlook is presented with a discussion on the chances and challenges facing PFETs and PSCs in their future commercial applications.

2 ADVANCED PFET MATERIALS

As mentioned above, as a key element of PFETs, the properties of semiconducting polymers, including the local intramolecular and the intermolecular packing between molecules, the molecular ordering and orientation at the semiconductor/dielectric layer as well as material itself directly affect the charge transport properties and thus the device performance. Thus, except of device structure optimization, the development of superior polymer semiconductors is crucial for the further enhancement of device performance. In order to obtain high device performance, polymer semiconductors should firstly meet some stringent criteria relating to the current carrying

and charge injection: (i) ideal coplanar structure conformation for maximized molecular orbital overlaps, (ii) good self-organization properties for preferable molecular orientation, especially at the semiconductor/dielectric interface, and (iii) proper energy gap and energy alignment for efficient charge injection as well as high ambient stability resistance to environmental O_2 or H_2O molecules.¹⁴ Moreover, the solubility, film-forming property, film morphology, and material purity are all also needed to be taken into account in designing a new high-performance polymer semiconductor. Recently, except for liquid-crystalline polymer semiconductors, easily processable, "annealing free," and "fabrication method independent" amorphous polymers have also received increasing attention for their promising commercial applications since its charge transport properties are isotropic in whole thin film along any direction and independent of fabrication conditions.^{23–25} Here, we will summarize these important and outstanding high-performing semiconducting polymers both for p-type and n-type from the viewpoint of novel molecular design.

2.1 High-Performance p-Type Polymers

2.1.1 Polythiophenes

Among the number of p-type semiconducting polymers, polythiophenes are one of the most and widely investigated materials, and the first OFET reported in 1986 was also based on the unsubstituted polythiophene.¹⁶ Since then, in a very long time, a large part of the research for polythiophene materials has focused on the improvement of solubility, exploration of easy synthetic methods, purification of materials, maximization of the molecular regioregularity, optimization of the molecular weight, and so on.^{26–28} Among all the polythiophene materials, regioregular poly(3-hexylthiophene) (P3HT) is the most representative semiconducting material with relatively high charge transport properties due to its highly crystalline microstructure as well as the very good solubility for solution processing.^{29,30} Various studies demonstrated that this mobility of P3HT device depended sensitively on the degree of head-to-tail (HT) regioregularity. For example, with high HT regioregularity (>91%) and low molecular weight, P3HT molecules generally preferentially

Figure 4 Two different orientations of ordered P3HT domains with respect to the FET substrate. The wide-angle X-ray scattering images are a color representation of the two-dimensional distribution of scattered Cu K α X-ray intensity from spin-coated, 70- to 100-nm-thick P3HT films with regioregularity of 96% (a) edge-on orientation and 81% (b) face-on orientation on SiO₂/Si substrates. The vertical (horizontal) axes correspond to scattering normal (parallel) to the plane of the film. The insets show schematically the different orientations of the microcrystalline grains with respect to the substrate. [Reprinted by permission from Macmillan Publishers Ltd: Nature (Ref. 31), Copyright (1999).]

form high orientation of crystalline domains with the backbone long axis in the plane and the π - π stacking direction parallel to the substrate (as shown in Figure 4a), promoting two-dimensional charge transport and resulting in high field-effect mobility of $0.1 \text{ cm}^2 \text{ Vs}^{-1}$; however, in contrast, with low HT regioregularity (81%) and high molecular weight, P3HTs tend to orient with their thiophene ring planes in the substrate plane and the π - π stacking direction normal to the substrate (as shown in Figure 4b), leading to low field-effect mobility ($\sim 10^{-4} \text{ cm}^2 \text{ Vs}^{-1}$).³¹ This important discovery sparks many new ideas in device science by optimizing the molecular orientation for high device performance. Kim *et al.*³² found that the preferential orientation of P3HT molecules in thin films could also be manipulated through controlling the intermolecular interactions at the interface between P3HT and the insulate substrate using self-assembling monolayer functionalized with various groups. For instance, on insulators with unshared electron pairs, such as $-\text{NH}_2$ or $-\text{OH}$, the P3HT chains tend to form with the edge-on molecular orientation in the films (Figure 4a), while on an insulator surface without unshared electron pairs, such as $-\text{CH}_3$, they tend to order with the face-on molecular orientation (as shown in Figure 4b), and the resultant different orientations were mainly attributed to the different interactions between the P3HT molecules

and the insulator surface, the existence of π -H interactions between the thienyl-backbone bearing π -system and the H (hydrogen) atoms of $-\text{NH}_2$ or $-\text{OH}$ modified surface facilitated the formation of edge-on molecular orientation in film and resulted in availability of as high as $0.3 \text{ cm}^2 \text{ Vs}^{-1}$ mobility. Additionally, it should be stated that the mobility of P3HT transistor is also affected by many other factors, such as molecular weight,^{33,34} solvent, film morphology,³⁵ and so on, and the approaches to improve the mobility of P3HT-based field-effect transistors are now still being reported; however, the poor stability of P3HT when exposed to oxygen and/or to water has been and continues to be a big barrier for it to commercialization, which mainly is induced by the oxidative instability because of its low ionization potential (IP is around 4.8 eV).³⁶

Recently, chemical modification of the thiophene backbone structure has been employed to provide the controlled manipulation of both the polymer backbone conformation and the microstructure as well as tuning the electronic energy levels of molecular orbitals.³⁶ One effective approach is to reduce the π -overlap by increasing the rotation freedom of the polymer backbone, such as by introducing unsubstituted thiophene units at the proper positions, which results in higher IP levels and simultaneously still retain good molecular orientation in the microstructure, and thus facilitates

the availability of high ambient stability as well as efficient charge transport properties. A prime example is poly(3,3''-dialkyl-quaterthiophene) (PQT), after thermal annealing this material could form highly ordered lamellar thin film microstructures by self-assembly due to the large local free-volume between adjacent alkyl side chains³⁷ and exhibited very high field-effect mobility of $0.2 \text{ cm}^2 \text{ Vs}^{-1}$ and good ambient stability due to the increased IP (4.9 eV).^{38,39} Another promising strategy developed to increase the IP of materials is to incorporate some electron-withdrawing groups or electron poor comonomers, such as perfluorobenzene, thiophene-fused aromatic/heteroarene rings, into the polythiophene backbone, which could result in a lower polymer highest occupied

molecular orbital owing to the reduced delocalization along the backbone, and meanwhile minimize any steric interaction between the neighboring alkyl groups and preserve the backbone planarity, which was very useful for the formation of highly ordered crystalline domains. On the basis of this consideration, various classes of high-performing polymer semiconductors with good ambient stability have been successfully produced. Among them, a copolymer of thieno(3,2-*b*)-thiophene and 4,4-dialkyl 2,2-bithiophene (PBTtT) reported by McCulloch *et al.*⁴⁰ in 2005 is an exemplary liquid crystalline semiconductor with excellent transistor property, good ambient stability, as well as unusual self-assembly properties for large crystalline domains. As shown in Figure 5, after annealing

Figure 5 AFM images of PBTtT-C12 (annealed at 180°C). (a) Before and (b) after annealing above the liquid-crystal isotherm. The left-hand side images show the topography and the right-hand side images show the phase image. The dark spots in the topography of the annealed film are voids where the film partially dewetted during annealing. [Reproduced from Ref. 40. © Nature Publishing Group, 2006.]

above its liquid-crystal isomer, PBTTT-C12 formed highly oriented polycrystalline structure with relatively large crystalline domains with diameter of around 200 nm, in which the backbone long axis oriented in the plane of substrate, and the thiophene ring plane ordered orthogonal to the substrate plane with high density of side chain interdigitation, promoting the formation of three-dimensional ordering and facilitating the efficient charge transport in films,⁴¹ which was also manifested by the extremely high charge carrier mobility of $0.2\text{--}0.6\text{ cm}^2\text{ Vs}^{-1}$ (even up to $0.72\text{ cm}^2\text{ Vs}^{-1}$ through optimizing the device structure with reduced channel length).⁴⁰ In contrast, PBTCT molecule, an isomer of PBTTT, exhibited lower field-effect mobility of $0.15\text{ cm}^2\text{ Vs}^{-1}$,⁴² further indicating the importance of molecular structure

itself in designing new high-performing organic semiconductors.

The successful molecular design concept for PBTTT further prompted the development of other high-performance polythiophene derivatives through simply tuning the molecular structure or incorporating more highly fused systems into the backbone under the combining consideration of processability, molecular organization, as well as the electronic properties in solid state. Poly(2,5-bis(2-thienyl)-3,6-di-alkylthieno[3,2-*b*]-thiophene) (PBT) has a similar molecular structure with PBTTT but different side chain positions. On annealing, the devices based on PBT exhibited a field-effect mobility of $0.25\text{ cm}^2\text{ Vs}^{-1}$ with a high on/off ratio of 10^7 .⁴³ Poly(2,6-bis(3-alkylthiophen-2-yl)dithieno[3,2-*b*;2',3'-*d*]thiophene) (PBTDT) exhibited a

Figure 6 Molecular structures of some representative polythiophene semiconductors.

very good solubility even in the environmentally friendly hydrocarbon solvents and also a very high crystalline properties with a close π - π stacking distance of 3.8 Å. BGBC PBTDT transistors demonstrated as high as $0.3 \text{ cm}^2 \text{ Vs}^{-1}$ field-effect mobility with on/off ratio of over 10^7 .⁴⁴ Poly(4,8-didodecyl-2,6-bis-(3-methylthiophen-2-yl)-benzo[1,2-*b*:4,5-*b'*]dithiophene) (PBTBT) is a typical low-temperature semiconductor, and without thermal annealing process, it could form highly structural thin films and exhibited very high field-effect mobility of $0.15 \text{ cm}^2 \text{ Vs}^{-1}$.⁴⁵ Further extending the π -system, Rieger *et al.*⁴⁶ and Fong *et al.*⁴⁷ designed and synthesized polymer P1 and P2TDC13FT4, respectively. P1 is also a low-temperature material and rendered easily processed with no need of long-term annealing, even on a flexible substrate this material still exhibited very high field-effect mobility of up to $0.5 \text{ cm}^2 \text{ Vs}^{-1}$.⁴⁶ With four fused thiophene rings in the backbone, P2TDC13FT4 possesses higher rigid rod property and closer π - π stacking distance of 3.76 Å, the obtained field-effect mobility was around $0.33 \text{ cm}^2 \text{ Vs}^{-1}$.⁴⁷ The molecular structures of polythiophene semiconductors are shown in Figure 6. The IP values and detailed information of field-effect performance for above-mentioned polythiophene materials are summarized in Table 1.

2.1.2 Copolymers

Recently, a number of groups have started to investigate the field-effect properties of other more complex polymer systems, such as copolymer with expectation of much higher device performance

and already obtained a certain achievement.^{17,48,50} A copolymer of cyclopentabithiophene and benzothiadiazole was initially designed as a low-band gap material for photovoltaic applications.⁵¹ In the early report, field-effect mobility of $0.17 \text{ cm}^2 \text{ Vs}^{-1}$ was obtained for the drop-casted thin film of CDT-BTZ with 2-h thermal annealing processing under 200°C , otherwise, only $10^{-4} \text{ cm}^2 \text{ Vs}^{-1}$ could be examined.⁵⁰ More recently, by further purification of the material and with higher molecular weight, approaching $1.4 \text{ cm}^2 \text{ Vs}^{-1}$ was achieved for CDT-BTZ in its dip-coated thin films, the author claimed that it was because of higher crystalline structures due to the purified material as well as the optimized fabrication process, which is also the highest field-effect mobility value reported so far for PFETs.¹⁷ Becerril *et al.*⁵² reported another donor-acceptor copolymer based on acenaphtho[1,2-*b*]thieno[3,4-*e*]pyrazine and fluorene (ACTP-F), which was designed for a good planar molecular structure to promote an intimate π - π stacking between polymer chains. In N_2 atmosphere, the best field-effect mobility of $0.2 \text{ cm}^2 \text{ Vs}^{-1}$ was achieved for ACTP-F-based transistors. Poly[*N*-9'-hepta-decanyl-2,7-carbazole-alt-5,5-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PCDTBT) is another example of photovoltaic material which was used to fabricate the field-effect transistors.^{25,53} The field-effect mobility examined for PCDTBT in PFETs was $0.03 \text{ cm}^2 \text{ Vs}^{-1}$. More importantly, PCDTBT-based PFET devices showed remarkable stability when exposed to elevated temperatures (in air stable up to 150°C and in N_2 stable up to 350°C , as shown in Figure 7a and c). However, in contrast, the mobility of P3HT decreased by more than two orders of magnitude after exposure to 200°C . Additionally, it should also be stated that the high-temperature stability of the transport mobility was strongly dependent on the molecular weight of PCDTBT, that is, the excellent thermal stability is observed for only the highest molecular weight materials, evidently indicative of degradation *via* reactive end groups (as shown in Figure 7b). It is proposed that such high thermal stability of PCDTBT is typically attributed to its fully aromatic backbone as well as the stability of amorphous structure, which provides very useful guidelines for further design and synthesis of new high thermal stable polymer semiconductors. The molecular structures of copolymers discussed above are shown in Figure 8.

Table 1 A summary of IP values and field-effect performance of above-mentioned polythiophenes.

Polymer	IP (eV)	$I_{\text{on/off}}$	Mobility (cm^2/Vs)	Reference
P3HT	4.8		0.28	32
PQT	4.9	$> 10^7$	0.14	38
		$> 10^7$	0.5	43
PBTTT	5.1	$> 10^6$	0.72	40
PBTCT	5.3	10^5	0.15	42

2.2 High-Performance n-Type Polymers

N-type materials are crucial for the fabrication of p–n junctions as well as complementary circuits. Over the past years, especially in recent years, there has been tremendous progress in the development of superior n-type semiconducting polymer materials, though the number of reported n-channel polymers in the literature is still far lower than the p-type polymers. Poly(benzobisimidazobenzophenanthroline) (BBL) is the first reported n-type semiconducting polymer and exhibited as high as 0.1 cm² V s⁻¹ electron mobility in air for its spin-coated ladder polymer films from Lewis acid solution.⁵⁴ However, BBL has very low solubility in common organic solvents, which significantly inhibited its potential applications. Recently, perylenes as one of the most interesting electron-depleted cores used for n-channel polymer materials have demonstrated great potential for n-type materials.⁵⁵ A new copolymer of *N,N'*-dialkyl-1,7-dibromo-3,4,9,10-perylene diimide and dithienothiophene (P(PDI2OD-DD)) was recently synthesized by Zhan *et al.*⁵⁶ and a good electron field-effect mobility of 0.02 cm² V s⁻¹ was measured based on top-contact device geometry (with alumina as source and drain electrodes) in vacuum conditions, unfortunately, the corresponding devices do not operate under the ambient condition. More recently, Chen *et al.*⁵⁷ found that a promising strategy to achieve both high-performance n-channel thin-film transistors and stable device operation in ambient conditions is to choose the larger electron affinity of naphthalene core replacing the perylene core in the copolymer backbone, which could stabilize the lowest occupied molecular orbital (LUMO) with a proper level in terms of both efficient electron injection and operation stability. And based on this consideration, they successfully produced a highly stable n-type polymer, P(NDI2OD-T2). A remarkable high electron mobility of approaching 0.85 cm² V s⁻¹ was achieved through optimizing the device architecture, dielectric layer, and channel length. This value is the highest electron mobility reported so far for polymer semiconductors and could also be comparable to amorphous silicon, representing a significant improvement on the benchmark values for n-channel polymers.⁵⁸ Moreover, the great versatile processing such as spin coating, by gravure, flexographic, and inkjet printing for

Figure 8 Molecular structures of some representative PFET copolymers.

P(NDI2OD-T2) along with the excellent electron transfer properties indicate its potential application in printed electronics. The molecular structures of n-type polymer semiconductors mentioned above are shown in Figure 9.

3 ADVANCED PSC MATERIALS

As mentioned previously in Section 1.3, BHJ solar cell structure has currently been the mainstream of research due to its maximum interfacial areas and

Figure 9 Molecular structures of some n-type polymer semiconductors.

efficient exciton diffusion, facilitating the further enhancement of device efficiency. There are generally two components of donor and acceptor materials in the active layer for BHJ structure and selection of the materials in both components is very important for the solar cell performance.

For acceptor materials, fullerene derivatives with solubilizing groups are the best candidates so far due to their high electron affinity, superior electron mobility, and three-dimensional structure, providing unique packing ability in blend to efficiently form electron transport channels.⁵⁹ Of them, [6,6]-phenyl-C₆₁-butyric acid methyl ester (PC₆₁BM) is the most important acceptor material, which exhibits excellent properties in fabrication of high-performance PSCs. However, weak absorption in the visible region and a low LUMO energy level for PC₆₁BM are its drawbacks, which significantly affect its contribution to light harvesting in the photovoltaic conversion and are unfavorable for availability of larger open circuit voltage (V_{oc}) in PSCs. Thus, some new soluble fullerene derivatives with stronger visible absorption and high LUMO energy levels than PC₆₁BM have been designed and synthesized. [6,6]-Phenyl-C₇₁-butyric acid methyl ester (PC₇₁BM) is one representative of such fullerene derivatives and shows improved

photovoltaic performance over PC₆₁BM in some cases.^{60–64} But the high cost of PC₇₁BM and other larger core fullerene derivatives⁶⁵ will probably limit their future commercial applications in PSCs. Recently, He *et al.*⁶⁶ reported a new C₆₀ derivative, indene-C₆₀ bisadduct with easier synthesis, better solubility, stronger absorption, and also better device performance in P3HT-based PSCs than PC₆₁BM, indicating it as a promising acceptor material for high-performance PSCs. Anyway, till date, polymer-based acceptors for high-performance PSCs have rarely been reported, though which are crucial for all-PSCs,⁵⁶ that is, the most effective component in BHJ solar cells is mainly based on properties of conjugated polymer donors in the blend. The molecular structures of representative fullerene derivatives used as acceptors are shown in Figure 10.

From the above discussion, it is obvious that the development of high-performance polymer donor materials for the active layer in PSCs has become crucial to achieve the desired solar cell performance for practical applications. Over the past years, many groups have made significant efforts in this field.^{60,62,67–69} Till date, the highest PCE reported for PSCs is approaching 8% based on a new polymer with alternating thieno[3,4-*b*]thiophene and

Figure 10 Molecular structures of some representative fullerene derivatives acceptors.

benzodithiophene units (PTB7)/PC₇₁BM system,²² which means a key breakthrough in PSCs. In this section, we give a review on the recent outstanding progress in developing new and promising active materials, especially those that have already shown promising performance in actual PSC devices, or have the potential to show significantly higher efficiencies than those recently achieved.

3.1 Polyphenylenevinylenes

Polyphenylenevinylenes (PPVs) are one of the most well-known conjugated polymer materials and have been widely investigated in many electronic and optoelectronic devices because of their unique light-emitting properties and photovoltaic performance. The original PPVs do not have enough solubility in organic solvents, so PPV derivatives with solubilizing groups, such as poly[2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylene vinylene] (MEH-PPV) and poly[2-methoxy-5-(3,7-dimethyloctyloxy)-1,4-phenylene vinylene] (MDMO-PPV), are usually used and have exhibited good photovoltaic performance. Till date, high efficiencies

of approaching 2.5% were achieved based on MDMO-PPV/PC₆₁BM blend, confirming the good photovoltaic performance for PPV derivatives.⁷⁰ In 2003, Wienk *et al.*⁶⁴ demonstrated improved efficiency of up to 3.0% for a MDMO-PPV/PC₇₁BM blend by changing the acceptor from PC₆₁BM to PC₇₁BM as well as adjusting the used solvent attributed to more efficient charge separation and the light harvesting, which is also the best efficiency reported so far for PPVs-based solar cells. Weak absorption in the visible region (only up to 500 nm) and the unstable properties in the presence of even small amount air are the main weak points for this class of materials, which dramatically limit the further improvement for their photovoltaic efficiency (because of low sunlight absorbance) as well as the potential applications. One simple design concept to improve the absorption and stability of PPVs is to introduce strong electron-withdrawing group, such as a cyano group into the PPV backbone. CN-PPV is one typical example, and compared with PPV, the highest occupied molecular orbital (HOMO) and LUMO levels of CN-PPV were lowered 0.6 and 0.9 eV, respectively, indicating its strong electron affinity as the polymer acceptors.⁷¹ The all-polymer

Figure 11 Molecular structures of representative polyphenylenevinylene materials used in PSCs.

BHJ solar cell based on MEH-PPV/CN-PPE blend exhibited PCE of 0.9%,⁷² another all-PSC based on P3HT/MEH-CN-PPV demonstrated quantum efficiency of 29% and an overall PCE of as high as 1.9% under a simulated solar spectrum, providing opportunities for plastic applications.⁷³ It is clear that although much progress has been made in this field, the efficiencies remained at 3.0% at best so far; thus, the general interest in this class of materials gradually faded especially over the past years. The molecular structures of PPVs are shown in Figure 11.

3.2 Polythiophene Materials

In recent years, polythiophenes, specifically speaking P3HT, have received particular attention as the electron-donating materials in polymer photovoltaic devices due to their superior physical properties, good solubility for solution processing, as well as the unique molecular structure facilitating self-assembly in solid state. In 2002, the first encouraging results for P3HT/fullerene derivative blend-based solar cells were reported by Schilinsky *et al.*⁷⁴ and as high as 8.7 mA cm^{-2} of short-circuit current density and good efficiency of 2.8% were achieved with a weight of 1:3 for P3HT and fullerene component. Since then, this experimental result significantly accelerated the development of P3HT-fullerene blend solar cells, and tremendous progresses have been made in this field over the past years, and relatively high efficiency of 4–5% recently could be easily achieved for P3HT/fullerene system in BHJ solar cells, which can be clearly illustrated by Table 2. Actually, on the other hand, such concentrated studies over the past years for P3HT/fullerene system-based solar cells also help us in understanding the optimization of device fabrication process better and also give some novel insights in design of new polymer donor materials to maximize the device performance. For instance, appropriate thermal annealing conditions could result in effective improvement for PSCs, probably due to both the molecular recrystallization as well as the reduced free volume and the density of defects.^{75–77} Another interesting discovery for P3HT-fullerene-based solar cells is about the influence of regioregularity on P3HT-based solar cell performance. Generally, in the same condition,

the highest molecular regioregularity of polymer could result in the highest device performance both for electronic³¹ and optoelectronic devices.⁷⁸ However, for P3HT-based solar cells, more recently, Sivula *et al.*⁷⁹ found that consciously decreasing the effective regioregularity of P3HT by incorporating a dihexylthiophene repeat unit in the backbone, poly(1-*co*-2), has not lowered the device efficiency but conferred more thermal stability with implication of long-term performance compared to the pristine P3HT-based solar cells, due to the obtainability of stable interpenetrating network of electron donor and acceptors in poly(1-*co*-2)/PCBM blend layer (as shown in Figure 12). Such discovery

that consciously decreasing the effective regioregularity of P3HT could not lower the device efficiency but confers more thermal stability breaks the traditional views that only pursuing high regioregularity in molecular design and sparks new ideals for designing new high performing even high thermal stable polymer materials.

Anyway, in the past decade, P3HT/fillerene system in BHJ solar cells has been the research focus and PCE of 5.0% has been achieved since 2005 (as shown in Table 2).^{77,81,82} However, in the long term, to realize the real commercial applications for PSCs, reaching the expected 10% efficiency is necessary.⁸³ Theoretical calculation

Figure 12 Transmission electron micrographs of annealed BHJ thin films containing 1:1 by weight RR P3HT:PCBM (a) and poly(1-*co*-2):PCBM (b). (c) Performance of photovoltaic devices fabricated with the control RR-P3HT or poly(1-*co*-2). The eight-device average PCE (η_{PC}) at standard conditions as a function of annealing time at 150 °C and typical *I-V* behavior (insets) observed after 30 and 300 min of annealing illustrate the difference between the materials. The error bars represent the 95% confidence interval of the average values. Inset is the molecular structure of poly(1-*co*-2). [Reprinted with permission from Ref. 79. demonstrated that assuming 100% external quantum efficiency for all photo energies above the 1.9 eV band gap of P3HT, the best possible P3HT-PCBM solar cell would produce roughly 17 mA cm^{-2} of photocurrent under AM 1.5 illumination, and combining the best open-circuit voltage (500 mV) and FF (0.6), the resultant highest power efficiency would be only 5.6%,⁸³ owing principally to the poor overlap between the P3HT absorption

and the solar emission spectrum (as shown in Figure 13).

3.3 Low-Band Gap Polymers

On the basis of the studies on 26 different polymer-PCBM BHJ solar cells, Scharber *et al.*⁶⁷ proposed a linear relationship between the V_{oc} and the used conjugated polymer oxidation potential,

Figure 13 Absorption coefficients of films of commonly used materials are depicted in comparison with the standard AM 1.5 terrestrial solar spectrum. [Reprinted with permission from Ref. 84. Copyright 2007 American Chemical Society.]

Figure 14 Contour plot showing the calculated energy-conversion efficiency (contour lines and colors) versus the band gap and the LUMO level of the donor polymer according to the model described above. Straight lines starting at 2.7 and 1.8 eV indicate HOMO levels of -5.7 and -4.8 eV, respectively. A schematic energy diagram of a donor PCBM system with the band gap energy (E_g) and the energy difference (ΔE) are also shown. [Reproduced from Ref. 67. © Wiley-VCH Verlag GmbH & Co. KGaA, 2006.]

which could be illustrated by (3). Where e is the elementary charge and using -4.3 eV for the PCBM LUMO energy and the value of 0.3 V is an empirical factor. Then, combining efficient equation (as shown in Figure 3b), the device efficiency can be predicted solely as a function of the band gap and LUMO level of the donor. On the basis of this important finding, and under the assumption of 65% FF and neglecting any contribution from photons absorbed by the fullerenes, they further calculated the expected efficiency as the function of the band gap and the LUMO level of the donor, which is clearly shown in Figure 14. It is clear that if improving the device efficiency of around 10%, the donor materials in BHJ solar cell must meet the requirements with a smaller band gap (<1.74 eV) and an appropriate LUMO level of <-3.92 eV, while this is impossible for the original P3HT just through device fabrication optimization.

$$V_{OC} = \left(\frac{1}{e}\right) (|E^{\text{donor}} \text{HOMO}| - |E^{\text{PCBM}} \text{LUMO}|) - 0.3 \text{ V} \quad (3)$$

The requirements for donor materials described above in polymer-fullerene in BHJ solar cells suggest that development of new polymer systems with low band gap as well as an appropriate LUMO energy level is recently the most promising strategy for the further improvement of device performance. Over the past several years, a large amount of effort has been devoted to this field research and remarkably important progresses have been made. And the highest PCE reported for PSCs is approaching 8%, representing a key breakthrough in PSCs. Figure 15 shows the molecular structures of some representative low-band gap donor materials with PEC $>5\%$ in combination with PCBM characterized in the BHJ solar cell structure.

Poly[2,6-(4,4-bis-(2-ethylhexyl)-4-cyclopenta[2,1-*b*;3,4-*b'*-dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBT) is the first low-band gap material with an extremely low E_g of ~ 1.5 eV, corresponding to a wide spectra region to the near infrared spectra (850 nm) and is very suitable for efficient light harvesting charge carrier extraction in PSCs.^{51,85} In the early report, efficiency of up to 3.2% was roughly obtained for PCPDTBT/PC₇₁BM blend BHJ solar cells; however, the devices suffered from short carrier lifetimes and considerable

recombination probably due to the nonoptimized phase separation.⁵¹ With the ideal of incorporating a few volume of alkanedithiols in the blend to optimize the films morphology, Peet *et al.*⁸⁶ further significantly improved the device performance reaching an efficiency of up to 5.5% under 100 mW cm^{-2} together with V_{OC} of 0.62, FF of 0.55, and J_{sc} of 16.2 mA cm^{-2} for PCPDTBT-based solar cell, the values of which was further certified by Konarka by submitting a device to NREL with a return certification of $\sim 5.2\%$ efficiency.

Taking the use of the superior properties for carbazole-based copolymer⁸⁶ and the larger open-circuit characteristics for polyfluorene (PF)-based copolymers in solar cells,⁸⁷ recently many new copolymers based on PF and carbazole groups have been successfully developed.⁸⁸ Interestingly, with N or Si atom replacing the bridging C atom of PF core, not only the efficiency performance but also the thermal stability has been remarkably improved. PCDTBT (as shown in Figure 8) and PSiF-DBT are two of the most representative examples. Under standard measurement condition with AM 1.5 irradiation and light intensity of 100 mW cm^{-2} , the PCDTBT/PC₇₀BM solar cells exhibited high efficiency of approaching 6%, along with J_{sc} of 10.6 mA cm^{-2} , V_{OC} of 0.88 V, and FF of 0.66, this value of results has also been well certified by Konarka with a return back efficiency of 5.96%.⁵³ Similarly, very high efficiency of 5.4% with J_{sc} of 9.5 mA cm^{-2} , V_{OC} of 0.90 V, and FF of 0.51 was achieved for PSiF-DET/PC₆₀BM-based solar cells under AM 1.5 illumination with an irradiation intensity of 800 mW cm^{-2} .⁸⁸ In order to achieve a planar polymer conformation for better chain packing in films with expectation of a positive impact on the charge transport properties, Qin *et al.*⁶⁹ developed another new such kind of copolymer, poly(2-(5-(5,6-bis(octyloxy)-4-(thiophen-2-yl)benzo[*c*][1,2,5]thiadiazol-7-yl)thiophen-2-yl)-9-octyl-9H-carbazole) (HXS-1) just through cleverly tuning the positions of side chains, that is, with two octyloxy chains on the benzothiazole ring and an octyl chain on the carbazole ring. HXS-1 films exhibited highly crystalline nanostructure with a close π - π stacking, facilitating its efficient charge transport with hole mobility of around $0.06 \text{ cm}^2 \text{ V s}^{-1}$ estimated by PFETs.⁸⁹ Relative low band gap as well as excellent charge transport properties together contributed to the high efficiency of up to 5.4% for BHJ solar cells based on HXS-1/PC₇₁BM blend.

Figure 15 Molecular structures of some representative low-band gap donor materials with PCE > 5% in combination with PCBM characterized in the BHJ solar cell structure.

More recently, Liang and Yu⁶² developed a new class of excellent low-band gap polymers based on thieno[3,4-*b*]thiophene and benzodithiophene alternating units, named as PTBx. These materials have relatively low band gaps (from 1.70 to 1.85 eV) and exhibit efficient absorption throughout the region of greatest photo flux in the solar spectrum (around 700 nm) due to the stabilization of quinoidal structure in the backbone. Additionally, good self-assembly properties for high hole mobility, proper side chains for good solubility and miscibility with fullerene components, and flexible

structure tuning properties for the availability of relatively low-lying HOMO energy levels make this series of materials well fulfill the requirements for high efficient solar cells. Among them, BHJ solar cells based on the blend of PTB7 with PC₇₁BM exhibited unprecedented efficiency of 7.4%, which is also the highest PCE for PSCs reported so far and represents a big breakthrough in developing high-performance PSCs.

Additionally, with the organometallic as the donor materials in photovoltaic devices has also intrigued people's attention in the last decade;

Table 3 Electronic energy levels and the highest photovoltaic performance reported so far for above-discussed low-band gap polymers.

Polymer	E_g^a (eV)	E_{HOMO} (eV)	E_{LUMO} (eV)	V_{oc} (V)	J_{sc} (mA cm ⁻²)	FF	PCE ^b (%)	Reference

however, in the early report, the PCE is absolutely low probably due to the larger band gap and unoptimized device structure.^{90,91} On the basis of the previous studies, Wong *et al.*⁹² recently created a new platinum(II) polyyne polymer based on 4,7-di-2'-thienyl-2,1,3-benzothiadiazole as a core component (P2). By optimizing the fabrication process, the BHJ solar cells containing P1/PCBM blend exhibited the best PCE of approaching 5%, an open-circuit voltage of 0.8 V, and a FF of 0.40, indicating a new concept to apply low-band gap metallated conjugated polymers as the donor materials for high-performance solar cells. The molecular structures of low-band donor materials are shown in Figure 15. A brief summary of electronic energy levels and the highest photovoltaic performance reported so far for the above-discussed low-band gap polymers is presented in Table 3.

4 PROSPECTIVE DEVICE APPLICATIONS

The most attractive advantage for conducting and semiconducting polymers is their feasible solution processing, which makes them offer promising opportunities for a vast array of flexible, low-cost and large-area electronic, and photonic applications, such as organic complementary circuits, display drivers, solar cells, and photodetectors.^{5,9,93} As mentioned above, over the past years, tremendous progress has been made in the development both of PFET and PSC performance, and as high as 1.4 cm² Vs⁻¹ for PFETs or approaching 8% efficiency for PSCs has been achieved, the values of which have already been comparable to that of amorphous silicon devices. However, because of many problems relating to the device stability, device fabrication techniques, and so on, there is

still a large space for PFETs and PSCs to fully realize their commercialization. So, in parallel research of developing high-performing functional polymer materials, many studies from the laboratories and well-known big companies have already started to focus on exploiting their prospective applications in electronics and photonics, especially in terms of optimizing device fabrication processing and lowering the cost. Here, the prospective electronic and photovoltaic applications are presented, representing a promising development in these fields.

4.1 Low-Cost Polymeric Complementary Circuit

OFETs offer potential to form low-cost building blocks for large-area electronic devices, especially on flexible substrate.⁹⁴ Till date, various organic complementary circuits based on small organic molecules have been fabricated through vacuum deposition technique or metal electrodes.⁹⁵ However, from the viewpoint of low-cost, high-performing semiconducting polymers with good solubility are preferable for large-area electronics, even though the mobilities are generally one order lower than their small molecular counterparts.^{5,9,93} Actually, the early all-polymer transistor has come out in 1994, through laying down the semiconducting molecules and electrodes using the disruptive and simple printing technique.⁹⁶ Since, a large amount of effort has been made in integrating the individual all-polymer transistor into fully integrated functional circuits.^{94,97} However, low carrier mobility for polymer semiconductors has significantly hindered switching rate of the complementary logic products. The availability of

Figure 16 P3HT (p-channel)-P(NDI2OD-T2) (n-channel) complementary inverters. (a) Schematic electrical connections of the inverters, and optical image of the gravure-printed device before common gate deposition. (b) Static switching characteristics of the inverter where both the semiconductors and the indicated dielectrics are gravure-printed (insets, gain of the corresponding device). Insets in (c) and (d) are expanded views with the same axes as the main plots. [Reproduced from Ref. 58. © Nature Publishing Group, 2009.]

high-performing n-type polymer semiconductor, P(NDI2OD-T2) provides the potential to form high-performance complementary all-polymer inverters. Additionally, P(NDI2OD-T2) also exhibits a very good chemical stability, large solubility in common organic solvents as well as feasible processing with versatile inexpensive techniques, such as gravure, flexographic, and inkjet printing. Figure 16 shows the static switching characteristics of all-polymer P3HT (p-channel)-P(NDI2OD-T2) (n-channel) complementary inverters through different fabrication processing and as high as 25–60 voltage gains were demonstrated, providing promising opportunities for high-performing flexible, large-area plastic electronics.⁵⁸

4.2 Roll-to-Roll Technique for Plastic Solar Cells

In another parallel research, much efforts have also been made in driving PSCs to their commercialization, especially in terms of the

operation stability in a large-scale, cost analysis for whole fabrication process as well as versatility of techniques, and so on. In this field, Krebs and his colleagues have made important contributions to the development of feasible, effective solution-processing methods.^{98,99} More recently, Krebs has developed a roll-to-roll process technique for monolithic large-area PSCs, which is free from the indium-tin-oxide electrode and significantly reduces (lowers) the processing costs compared to other fabrication techniques (as shown in Figure 17). In this process, a commercially available kapton foil with an overlayer of copper was used as the substrate. First, by sputtering of titanium metal onto the kapton/copper in an R2R vacuum process gave the monolithic substrate and back electrode for the devices. Then, the active layer was slot-die coated onto the kapton/Cu/Ti foil followed by slot-die coating of a layer of PEDOT:PSS. Importantly, no patterning of the first four layers was necessary and only the final front electrode required a pattern. The front electrode was applied by screen printing a protective layer in the areas

Figure 17 (a) R2R lamination of the modules and (b) a picture of the modules when cutting into sheets and final cells. (a) The large cell has nominal outside dimensions of 150×150 mm and the small cells have nominal outside dimensions of 70×70 mm. (c) A 4×5 array of the 70×70 mm² cells (the scale bar is 64-cm long with divisions every 10 cm). (d) Typical I - V curves for one of the 7×7 cm cells when illuminated through a 7×7 cm mask. [Reproduced from Ref. 99. © Elsevier, 2009.]

for front electrode contacts and a firetec silver grid was applied by screen printing. The topology of the device and the choice of fin grid electrode geometry allowed for serial connection of the individual cells into modules. The individual cells were as large as 150×150 mm. Through this method, as high as 74% FFs was achieved for the produced PSCs, which is much higher than that is readily achieved using serially connected cells on the same substrate, indicating its promising applications after further improvement in terms of volume and speed, device efficiency, supporting

temperature, as well as limitation. Anyway, it is a breakthrough in technology for PSCs.

5 CONCLUSION

In conclusion, with the significant effort, the performance of PFETs and PSCs has received great progress and has already been comparable to amorphous silicon in laboratory experiment and the small prototype device. However, to realize

their real commercialization, further development in both high-performing functional materials and optimization of various flexible and effective techniques is needed. Especially, in technology, significant effort to effectively integrate the discrete device to complex circuit is required. The device's operational stability and lifetime need to be improved and the fabrication costs have to be lowered. Anyway, polymeric electronics and photovoltaics are beginning to show us their significant potential and the bright future in low-cost, large-area, especially on flexible substrate applications.

Silicon Radical Surface Chemistry

Bart Rijkse, Mabel A. Caipa Campos, Jos M. J. Paulusse and Han Zuilhof

Laboratory of Organic Chemistry, Wageningen University, Wageningen, The Netherlands

1 INTRODUCTION

Radical chemistry is the method of choice for the preparation of numerous organic molecules and polymers, as well as inorganic complexes. It has also found its way into the area of surface science. In particular, the radical chemistry of silicon surfaces has attracted much attention because of the relative ease of application, that is, mild reaction conditions, high chemo- and regioselectivity, and the absence of metal catalysts, with no formation of by-products.^{1–4} This article reviews the different aspects of the radical chemistry involved in making organic monolayers on silicon surfaces, specifically Si–C-linked monolayers.

Ever since the development of the first integrated circuit in 1958, the demand for novel semiconductor-based electronic devices with ever-smaller dimensions has been continuously increasing. Silicon and germanium are the preferred metalloids because of their semiconductor properties and tunable electron mobility, and current state-of-the-art devices have reached feature sizes below 30 nm. As a consequence, the impact of surface effects is becoming increasingly important.^{2,3,5} The surface chemistry associated with these semiconductors, silicon in particular, has been explored as a potential means toward the fabrication of molecular electronic devices.^{6,7} For many sensitive electronic applications, however, it is also important that the silicon surface remains oxide-free.^{8–10} Silicon oxide acts as an insulator, and a thin layer of oxide on top of

a silicon-based electronic device prevents direct electronic contact between the organic functionality and the substrate, thereby reducing the signal intensity. Controlling the nature of the surface can be achieved in a number of ways, of which the attachment of self-assembled monolayers (SAMs) may be considered the most sophisticated.^{11–15} Such monolayers allow for the precise attachment of (bio)molecules and the subsequent detection of their counterparts. Moreover, high-quality SAMs may also prevent oxygen and water from reaching the surface, thereby improving the lifetime and robustness of such sensing devices.

Whereas the familiar SAMs on gold¹⁶ are mostly based on the reversible gold–thiol bond, SAMs on silicon are covalently attached to the surface.^{2,3,5} In effect, obtaining high-quality monolayers is not trivial. Siloxane-based SAMs are commonly applied in order to attach functional molecules onto silicon substrates in a rapid way, but these bonds are prone to hydrolysis and do not provide for oxide-free silicon substrates.^{17–20} The use of monolayers based on silicon–carbon bonds offers an exciting alternative. Si–C bonds are known to be both thermally and chemically robust because of the low polarity of this strong bond. This is essential for the formation of well-defined, highly stable, and robust organic monolayers on silicon.^{2,21}

In this article, various methods for the preparation of organic Si–C monolayers, including relevant issues concerning oxidation of the silicon surface, are presented. The radical mechanisms at the silicon surface based on experimental and

theoretical studies are discussed. In addition, the importance of high-quality oxide-free monolayers on silicon surfaces, as well as the introduction of functional groups to the monolayer, is addressed. Finally, applications and future research are presented, describing the main remaining challenges.

1.1 Silicon Surfaces

Two types of silicon are most commonly used: flat (single crystal) and porous silicon surfaces. The most widely employed type is flat silicon because of the variety of orientations possible, the possibility of adding dopants in a controlled manner, and commercial availability.^{1,22,23} The most common surface orientations are Si(100) and Si(111). Freshly cut surfaces are rapidly coated with a thin native oxide layer upon exposure to air.

The initial step in the formation of organic monolayers on silicon involves what may be called an *activating passivation of the silicon surface*, which opens up the surface reactivity to only a selected series of desirable reactions. In general, hydrogen is the most commonly employed passivating agent²⁴; however, halogens such as iodine and chlorine have also been investigated.^{25,26} Oxide-free, hydrogen-terminated silicon surfaces may be obtained via the adsorption of atomic hydrogen under ultrahigh vacuum (UHV) conditions at elevated temperatures ($>1100^{\circ}\text{C}$).²⁷ Alternatively, wet-chemical reactions using fluoride-containing solutions yield hydrogen-terminated silicon surfaces under rather mild conditions (i.e., ambient temperature and pressure). Important features of these hydrogen-terminated silicon surfaces include their high chemical homogeneity ($>99\%$ H-termination), their relative stability in air and water during brief rinsing procedures, and their low reactivity toward several organic solvents.^{21, 28–31} Treatment of Si(100) surfaces with dilute aqueous HF (1–3%) yields predominantly dihydride-terminated Si(100) surfaces that display nanometer-scale roughness (Figure 1).²⁹ However, mono- and trihydride orientations are also present. The preparation of mono- and dihydrated atomically flat surfaces is possible only by employing UHV techniques. Recently, Hines and coworkers used scanning tunneling microscopy (STM) and Fourier transform infrared spectroscopy (FTIR) to demonstrate that

Figure 1 Preparation of hydrogen-terminated Si(100) and Si(111) surfaces by chemical etching in fluoride-containing solutions.^{28,29,32,33}

an aqueous solution of NH₄F (40%) selectively passivates Si(100) surfaces, eventually producing a hydrogen-terminated surface of near-atomic flatness.³²

Conversely, after only a brief immersion of the Si(111) surfaces in degassed aqueous NH₄F solution (40%), atomically flat surfaces, nearly exclusively occupied by Si–H groups, are readily obtained (Figure 1).^{28,29} The roughness of the surface has been studied by STM and FTIR spectroscopy. The attenuated total reflection-FTIR (ATR-FTIR) spectra of the hydrogen-terminated Si(111) surface show a very sharp and narrow silicon–hydrogen stretching vibration $\nu(\text{Si–H})$ at 2083.7 cm^{-1} , indicating a high degree of chemical homogeneity, while the STM image of the silicon surface shows atomically flat terraces with monoatomic steps (Figure 2).

In addition, the etching mechanism has been resolved on the basis of *in situ* STM and electrochemical measurements. Etching involves two components: one chemical and the other electrochemical; both are highly dependent on pH.^{34,35} Other passivating agents can be employed, such as HF and NaOH; however, these treatments lead to increased surface roughness, as well as the formation of mono-, di-, and trihydride-terminated Si(111) surfaces.^{36,37}

Other silicon surfaces, such as porous silicon, are also of great interest owing to their luminescent properties and high surface area.³⁸ These surfaces are prepared from crystalline silicon substrates (mainly Si(100)) using chemical or electrochemical methods. Surfaces typically consist of $-\text{SiH}_3$, $=\text{SiH}_2$, and $-\text{SiH}$ groups in different orientations and environments. Over the last few years, porous silicon has attracted much attention as a

Figure 2 (a) ATR-FTIR spectra of the hydrogen-terminated Si(111) surface, prepared through the 40% NH_4F (aq) etching procedure, taken with both s- and p-polarized IR light. (b) STM image of the flat Si(111)-H surface, prepared through etching with 40% NH_4F (aq). The gray scale represents a height change of 0.5 Å. [Reprinted with permission from G. S. Higashi, R. S. Becker, Y. J. Chabal, A. J. Becker, *Appl. Phys. Lett.*, **58**, 1656–1659, (1991). Copyright 1991, American Institute of Physics; and G. S. Higashi, Y. J. Chabal, G. W. Trucks, K. platform for biomolecules.³⁹ The refractive index can be tuned, turning the substrates into photonic devices,⁴⁰ which can be subsequently modified by the attachment of complex biomolecules.^{39–42}

1.2 Oxidation of Silicon Surfaces

The oxidation of hydrogen-terminated silicon surfaces has been studied in detail.⁴³ However, the mechanism has still not been completely unraveled. Currently, the most accepted mechanism involves a radical route, analogous to the auto-oxidation of tris(trimethylsilyl)silane $(\text{TMS})_3\text{SiH}$ or TTMSS (see **Silanes as Reducing Reagents in Radical Chemistry**).⁴⁴ In this mechanism, molecular oxygen reacts with a surface-centered radical (surface **1**) to form the peroxy radical **2** (Figure 3).

This radical either abstracts a neighboring hydrogen, leaving a dangling bond at the surface (**3**), which may either react again with oxygen, or splits up under insertion of oxygen into a silicon backbond inside the surface (**4**). In the latter case, the silyloxy radical may abstract a hydrogen atom, resulting in a silanol group (surface **5**). Alternatively, this oxygen may be inserted in an available silicon backbond, resulting in surface **6**, the analog of which has been observed when TTMSS was employed in a model study.²³ Both situations result in the formation of dangling bonds at the surface which are prone to attack by oxygen.

The radical mechanism of oxidation of silicon surfaces was further investigated by FTIR.⁴³ The H-Si(111) surfaces were exposed to air, either in the dark or under irradiation at specific wavelengths. The intensity of the Si-H stretching vibration did not decrease significantly in the dark, or upon irradiation using 450-nm light. This is in agreement with the energy required for homolytic cleavage of Si-H bonds, which was found to be 84 kcal mol⁻¹,⁴⁶ requiring irradiation at wavelengths below 350 nm. This was further confirmed by a small decrease in signal observed upon irradiation at this wavelength, which is as expected, because 350 nm is apparently just barely enough for photolysis. Dramatic loss of the Si-H signal was observed upon irradiation at 254 nm, indicating that oxidation of the surface involves such homolytic cleavage of the Si-H bond. Interestingly, oxidation of porous silicon initially leaves the Si-H bonds intact, which shows that oxygen directly attacks the Si-Si bonds. FTIR spectra taken after irradiation of a freshly etched porous Si sample in the presence of oxygen ($\lambda = 365$ nm, 60 minutes) show a large increase of the silicon oxide band ($\nu_{\text{Si-O}}$ between 1000 and 1200 cm⁻¹) and a correspondingly loss of the

Figure 3 Oxidation of the hydrogen-terminated Si(111) surface.⁴⁵

SiH_2 signal ($\nu_{Si-H_2} = 2116\text{ cm}^{-1}$). However, the growth of the ν_{O-Si-H} band (2200 cm^{-1}) equals the loss of the SiH_2 signal, resulting in no net loss of the surface hydride species.⁴⁷ This difference in reactivity—which may be a reflection of slightly changed thermodynamics related to the surface structure of porous Si—also likely has consequences for the attachment of hydrocarbons to this substrate, via the occurrence of other reaction mechanisms.

2 RADICAL CHAIN PROPAGATION

Alkyl monolayers grown on appropriately prepared hydrogen-terminated Si(111) typically reflect the atomic flatness of the underlying silicon substrate. Several studies have focused on methods of chemical passivation of silicon through

formation of Si–C bonds.^{2,3,20,48} Hydrosilylation of alkenes or alkynes has been achieved via radical initiation,⁴⁹ thermally,^{49,50} or photochemically induced,^{43,51–53} or by utilizing Lewis acid catalysts.^{54,55} The first example of wet-chemical preparation of covalently attached organic monolayers on silicon surfaces, without an intermediate oxide layer, was reported in 1993 by Linford and Chidsey.⁵⁶ The carbon chains were bound to the hydrogen-terminated silicon surface via a radical reaction. Diacylperoxide is cleaved by pyrolysis (100°C) to form carbon-centered radicals (and CO_2), which abstract hydrogen from the surface, yielding surface-centered radicals (Figure 4). These silicon radicals in turn react with the abundantly present alkyl radicals to form stable Si–C bonds. As a result, densely packed monolayers were obtained, which showed good resistance to boiling chloroform, acids, bases, and even treatment with HF.

Figure 4 Formation of alkyl radicals from diacyl peroxide.

2.1 Attachment of Alkenes to Silicon Surfaces

Addition of alkenes and alkynes to silyl radicals was reported as early as 1947.^{57–59} This reaction proved very useful in the synthesis of organosilicon compounds (specifically from trichlorosilanes). Because of their reactivity toward silyl radicals,⁶⁰ alkenes and alkynes were used in a follow-up study on monolayer formation on silicon. Indeed, these compounds yielded high-quality monolayers in the absence and presence of various concentrations of diacyl peroxide. Deuterium labeling of the peroxide demonstrated that the attachment of unsaturated carbon chains is preferred over attachment of alkyl radicals stemming from diacyl peroxide. Moreover, at higher temperatures ($>150^{\circ}\text{C}$), dense monolayers were also obtained from alkenes in the absence of diacyl peroxide.⁴⁹ Formation of surface radicals was explained by either homolytic cleavage of the Si–H bonds or reaction with adventitious oxygen. As is known from the literature, radical addition to a double or triple carbon–carbon bond results in the formation of a β -carbon radical.⁶¹ This radical subsequently abstracts a hydrogen atom, either from unreacted olefin in solution or from an adjacent Si–H site. However, the latter is preferred, owing to the lower bond dissociation energy of 84 kcal mol^{-1} for Si–H⁶² in comparison to the terminal C–H bond in alkenes and alkynes (101 and 111 kcal mol^{-1} , respectively⁶³); this finally results once more in a surface-centered radical. Chidsey and coworkers proposed a radical chain reaction, which is depicted in Figure 5.⁴⁹ The feasibility of hydrogen transfer from the surface to the alkyl chain was later demonstrated on porous silicon by the group of Buriak.⁶⁴ After attachment of perdeuterated styrene to a hydrogen-terminated surface, they observed methylene vibrations at 2917 and 2846 cm^{-1} according to FTIR corresponding to consumption of Si–H sites.

Additional evidence for the radical propagation reaction was obtained from STM studies performed

Figure 5 Reaction mechanism of the addition of 1-alkenes to hydrogen-terminated Si(111), as proposed by Chidsey and coworkers.^{49,65}

Figure 6 Growth of styrene lines on a hydrogen-terminated Si(100) surface with a small number of single Si dangling bonds. A sequence of STM images is shown for prolonged exposure to styrene: 3 L (a), 28 L (b), 50 L (c), and 105 L (d). White arrows denote two particular dangling-bond sites, leading to growth of long styrene lines. The missing dimer defect (marked M) terminates line growth in the top left-hand corner of the image. [Reprinted by permission from Macmillan Publishers Ltd: Nature (Ref. 66), copyright (2000).]

under UHV on Si(100). To this purpose, dangling bonds (basically surface-centered silyl radicals) were created at the surface with an STM tip, which subsequently were exposed to styrene. STM showed lines of attached styrene molecules growing from these dangling bonds (Figure 6).⁶⁶ Growth of these lines halted at surface defects, supporting the proposed hydrogen abstraction mechanism. The observed pattern originates from the geometry of the hydrogen-terminated Si(100) surface, which consists of parallel-aligned SiH₂ sites, as shown in Figure 7.

Further evidence for the radical propagation mechanism was provided by Wolkow and coworkers, who studied the attachment of styrene on Si(111) with STM (Figure 8).⁶⁵ In this case, the reaction of styrene with dangling bonds at the surface led to the formation of islands. This indicates unidirectional growth of the monolayer, dictated by the geometry of the surface. The

Copyright American Chemical Society, 2002.]

hexagonal array of Si–H sites on atomically flat terraces provides for six equivalent Si–H sites near any starting Si–H site at the surface. From a single alkylation site, the reaction thus propagates via one of these available Si–H sites, in six possible directions, as observed in Figure 7. This chain reaction was found to be self-limiting, and is proposed to terminate when no neighboring hydrogen atom is available for abstraction by the alkyl radical, for instance, because of the chain running into itself. Additional studies performed by Zuillhof and coworkers, based on alkyl monolayers fabricated from alkenes via white-light-induced reaction, showed that island formation on Si(111) is generic for this kind of reactions, and is thus neither specific for styrene nor requires the use of an STM tip to induce a radical reaction.⁶⁷ Monte Carlo simulations showed that, on average, 76 chains attached to the surface before the chain reaction terminated.⁴³

2.2 Surface Reactions of Vinyl Radicals

The attachment of alkyne moieties to the surface form a special case, since the resulting product, which is obtained after addition and subsequent hydrogen transfer, is an alkenyl group. This unsaturated carbon is able to react again with a neighboring silyl radical, forming bridged Si–C–Si or Si–C–C–Si structures.⁶⁸ This reaction competes with the hydrosilylation of alkyne molecules present near the surface; this would then leave alkenyl chains at the surface (Figure 9, reaction a). However, alkyne monolayers on Si(100) did not show the presence of double bonds (no absorption between 1500 and 1700 cm^{−1} according to ATR-FTIR studies), indicating saturation of the alkyl chains. There are two additional possibilities for double attachment of alkynes, as depicted in Figure 9 (routes b and c).⁶⁸ The first route involves the formation of a 1,2-bridged structure

Figure 9 Reaction of alkynes with silicon surfaces: (a) Si(100); (b) Si(111).

obtained after reaction of the β -carbon in the double bond with the surface radical, resulting in a seven-membered ring (route b). Attachment via the α -carbon (route c), on the other hand, follows an anti-Markovnikov mechanism resulting in a six-membered ring. Route a is less favorable, since it does not follow for anti-Markovnikov type of addition, which is typically observed in reactions of silyl radicals.⁶¹ In addition, this route leads to the formation of a seven-membered ring, which is less favorable than a six-membered ring. The high strain is mainly located on the Si–C and C–C bonds, as the silicon atoms are constrained within the crystal lattice. Moreover, density functional theory (DFT) calculations confirmed that 1,1-bridged species are 5–7 kcal mol^{−1} lower in energy than 1,2 conformations.⁶⁸ It is important to note that both attachment modes are expected, since the energy differences are easily overcome at the high temperatures employed in these experiments. The characteristics of these alkyne-derived monolayers differ from those of alkene-derived monolayers prepared under these circumstances on H–Si(100) with respect to the tilt angles, which are on average higher for alkyne-derived monolayers (40°, 27°, and 33° for C12, C16, and C18-alkynes, as compared to 32°, 39°, and 18° for the alkene-analogs). For the more recently developed reactions that take place under milder conditions on H–Si(111),⁶⁹ precisely

the opposite is observed, pointing to the idea that attachment in those cases indeed only involves the terminal carbon atom, while here several bonding schemes are simultaneously operative (see Section 3.3.3).

On Si(111) surfaces, double α -attachment is unlikely, since the resulting bridged structure would form a highly strained four-membered ring. On the other hand, β -attachment would yield a five-membered ring, which is significantly lower in energy than the four-membered ring, though still too high in energy to form. Mono-attachment of alkynes as depicted in Figure 9b is therefore considered to be predominant. The presence of a C=C double bond in alkyne-derived monolayers on Si(111) was demonstrated by FTIR spectroscopy (C=C stretch at 1600.8 cm^{−1})⁴⁹ and by infrared reflection absorption spectroscopy (IRRAS) (C=C stretch at 1601 cm^{−1}).^{69,70}

2.3 Siloxyl Monolayers

Siloxyl monolayers are generally prepared by reacting chlorosilanes⁷¹ or trialkoxysilanes^{72–74} with an oxide-covered silicon surface. However, as a result of the poorly defined underlying silicon oxide surface, the resulting monolayers are less uniform than

Figure 10 Formation of siloxyl monolayers from (a) aldehydes and (b) alcohols.

alkyl monolayers linked via Si–C bonds. Several groups have reported solutions to this problem by attaching α -alcohols^{75–77} or aldehydes directly onto oxide-free silicon.^{76–79} Although both moieties lead to the formation of Si–O–C linkages, the mechanisms of formation are entirely different. The attachment of a carbonyl moiety to the silicon surface is expected to proceed via a very efficient radical chain mechanism, similar to the reaction with unsaturated alkyl chains (Figure 10a). In the case of alcohols, attachment is likely to proceed via nucleophilic attack of the OH group to the silicon, leading to a pentavalent silicon intermediate. Subsequent release of di-hydrogen results in oxidative addition. Attachment via this pathway does not lead to the formation of a new reactive site, as is the case in the radical chain mechanism. This mechanism is consequently less efficient, resulting in an overall slower and incomplete monolayer fabrication, as elegantly shown for the attachment of methanol to Si(111) upon prolonged heating at elevated temperatures (65 °C, 12 hours), which leads to partial coverage of the surface (max. 33% of available Si–H sites).⁸⁰

2.4 Competing Reactions by Halogen Impurities

Neat alkenes and alkynes may easily contain traces of the starting material such as bromo or chloro alkanes. From the experiments performed by Chatgililoglu and coworkers, it is known that silyl radicals can react very fast with such halocarbons (see **Silanes as Reducing Reagents in Radical Chemistry**). The rate of reaction of a primary alkyl bromide toward the TTMSS radical

Figure 11 Bromine impurities in the reaction mixture lead to the formation of Si–Br, causing holes in the monolayer. Furthermore, the surface-bound bromine is susceptible to hydrolysis, leading to oxidation of the surface.

is in the order of 10^7 s^{-1} , whereas the chlorides react much slower (10^5 s^{-1}).⁸¹ The reactivity of bromine compounds easily overshadows that of aldehydes, alkenes, and alkynes, which are in the range of 10^4 – 10^6 s^{-1} . Traces of bromoalkanes present in the reaction mixture lead to holes in the monolayer (Figure 11). These Si–Br sites are susceptible to hydrolysis, resulting in oxygen bound to the silicon surface, which, for certain applications, is undesirable and decreases monolayer stability.

The reactivity of silyl radicals toward chlorocarbons is much lower (as described above), and lies within the range of those of aldehydes and alkenes. This may explain the fact that traces of chlorine compounds are typically not a big problem in monolayer formation. Even at a higher

concentration of such chlorine compounds present in the reaction mixture, no significant chlorination of the surface was observed.^{49,82} It is, in fact, quite possible to make chlorine-terminated carbon monolayers ($\text{Si}-(\text{CH}_2)_n-\text{Cl}$) from chlorine-containing compounds such as 1-chloroundecene, and such Cl termination was reported to be of good quality.² However, when high-quality oxide-free surfaces are required, chlorine traces still may cause undesired holes in the monolayer, which may facilitate oxidation.

3 FORMATION OF SURFACE-CENTERED SILYL RADICALS

3.1 Thermal Attachment

As previously mentioned, initial experiments demonstrated that monolayer formation also takes place at elevated temperatures ($>200^\circ\text{C}$) with linear alkenes C_nH_{n+2} ($n = 12\text{--}20$), and does not require the use of peroxides.⁴⁹ Zuilhof, Sudhölter, and coworkers showed the formation of high-quality alkene monolayers on silicon by employing a solution of alkene (2.5%) in toluene or mesitylene.³¹ The use of alkene solutions signifies a reduction of the amount of material required per wafer (40-fold), and allows the use of solid alkenes. This thermal method for monolayer formation on silicon is fast, yields high-quality monolayers, and is relatively easy to employ. However, owing to limitations in the thermal budget, the required temperatures limit the application of this method in ultrasmall integrated circuit (IC) manufacturing.² In addition, the direct attachment of functional alkenes and complex molecules may lead to the formation of side products, or (to a varying degree) result in the so-called upside-down attachment (Figure 12), drastically influencing monolayer quality (i.e., density and uniformity). Typically therefore, these complex molecules are attached to a prefunctionalized surface. These procedures will be explained in more detail later. Side reactions may slow down the monolayer formation, resulting in incomplete layers. The occurrence of bare patches on the surface has major consequences for the monolayer stability, since these patches are not protected against oxidation.

Figure 12 (a) Side reactions of functional molecules as a result of high reaction temperatures; (b) undesired reactions at the surface and upside-down attachment and bridge formation.

3.2 UV Attachment

In the search for milder reaction conditions for the attachment of alkenes and alkynes, the use of UV irradiation was considered. Early work of Chidsey and coworkers already showed that UV irradiation of Si(111) and Si(100) surfaces resulted in direct cleavage of the Si–H bond.⁴³ In their study, they found that the drastically enhanced formation of SiO_2 as observed by X-ray photoelectron spectroscopy (XPS) coincided with a decrease in Si–H signal at 2112 cm^{-1} in FTIR. A range of alkenes and alkynes was successfully attached to the surface, yielding monolayers of comparable quality as those obtained via thermal reaction. This UV method has several advantages over thermal attachment, such as significantly lower input of the thermal energy required, as these reactions are performed at room temperature without increase of reaction times. Considering the aforementioned thermal budget, this method is very suitable for the IC manufacturing industry.² Arguably, the most important advantage is the ability to direct photopattern the surface. The use of a mask allows local irradiation, and thus local monolayer formation, as shown in Figure 13. This was demonstrated by the selective functionalization of H–Si(111) with octadecanal using UV irradiation through a mask ($\lambda = 385\text{ nm}$).⁷⁸ The remaining unmodified patches were shown to still be reactive by attaching 1-octadecene in a following step. The different wettabilities of the monolayer-covered areas and the uncovered silicon areas were observed under a microscope.

Figure 13 (a) Direct patterning via monolayer formation.⁷⁸ (b) patterning of oxide layer and subsequent filling of unmodified patches with a monolayer from 1-octadecene.⁸³

Interestingly, Wayner and coworkers successfully demonstrated the opposite approach by selectively oxidizing the silicon surface by irradiating through a mask under ambient atmosphere (Figure 13b). This resulted in oxidized, nonreactive patches, and nonirradiated reactive patches.⁸³ After growing a monolayer on the reactive patches, a pattern containing hydrophobic and hydrophilic domains was obtained, which was observed by scanning electron microscopy (SEM) and scanning auger electron microscopy (SAES), (Figure 14).

Side reactions also occur during UV-initiated monolayer formation. Photolysis of functional moieties may occur, and upside-down attachment has also been demonstrated, similar to the thermal methods.⁸⁴ Moreover, prolonged UV irradiation may cause cleavage of the Si–C bonds, resulting in degradation of the newly formed monolayers. This has also been observed for monolayers on porous silicon.^{55,85}

Bedzyk and coworkers have reported that, upon reaction with undecenoic acid bromoethyl ester, less than 10% of the ester was attached via the alkene moiety while retaining the bromine (Figure 15, A).⁸⁴ For the remaining sites, up to 50% reacted with bromine (B), 27% reacted with debrominated ester (C), and 13% showed upside-down attachment (D). Again the usefulness of these reactions depends on the application of the monolayer. When the function of the monolayer is simply to serve as a scaffold layer, and the resulting packing density and presence of surface oxides are not important, this method provides a fast and easy way to obtain such a layer.

[Reprinted with permission from Ref. 83. Copyright 2001 American Chemical Society.]

An alternative mechanism to the UV-induced cleavage of Si–H bonds was recently reported by Hamers and coworkers.⁵¹ They argue that UV irradiation leads to electron donation from the silicon surface into the acceptor levels of carbon–carbon double bonds present near the surface. This leaves a positive charge on the surface, in the form of a silyl cation, which is susceptible to nucleophilic attack (Figure 16). Attack of an alkene on this surface

Figure 15 UV attachment of undecenoic acid bromoethyl ester to silicon, resulting in normal attachment (A), bromination of the surface (B), normal attachment of a debrominated alkene molecule (C), and upside-down attachment of a debrominated compound (D).⁸⁴

cation and a (concerted or successive) hydride shift from the silicon surface to the carbon chain yield again a silyl cation, close to the alkylation center. This cation is available for a following nucleophilic attack. This proposed mechanism has, however, not yet been investigated in full detail.

3.3 Other Initiation Mechanisms

The need for more versatile and milder approaches toward obtaining functional monolayers on silicon still continues. Significant success has been achieved via the development of methods that make use of lower temperatures (<150 °C) or white light ($\lambda > 450$ nm),^{88–90} or even proceed without any significant external activation (i.e., at room temperature, in the dark),⁶⁹ frequently making these approaches, next to the toluene/mesitylene-based

method discussed before,³¹ the methods of first choice for Si–C based monolayer formation onto hydrogen-terminated Si. Since these conditions do not allow regular crossing of high activation barriers, direct cleavage of the Si–H bonds is not predominantly involved. Several mechanisms that have been proposed in order to explain mild attachment will be discussed in the following.

3.3.1 Initiation by Adventitious Oxide and Activation by Glass Reaction Vessels

The idea of adventitious oxide being able to create dangling bonds on the silicon surface dates back to the initial experiments performed by Linford and Chidsey.⁴⁹ In their experiments in the absence of radical initiator, they still observed efficient monolayer formation from alkenes and

alkynes. These reactions were attributed to the presence of traces of oxygen in the reaction mixture, which reacts with the silicon surface as previously described in Section 1.3. Although these reactions indeed result in the initiation of a radical chain reaction, recent studies show that the extensive exclusion of oxygen from the reaction mixture has no apparent influence on the reactivity.⁶⁹ In fact, the quality of the monolayers increases as oxidation of the surface is minimized. Therefore, still another initiation mechanism must be in operation that may coincide with oxygen initiation. On the basis of these findings, Miscki *et al.* proposed a mechanism that involves degradation of the unsaturated hydrocarbons by reaction with silanol groups of the glass reaction vessel at elevated temperature.⁹¹ This mechanism was supported by the observed drop in reaction rate and monolayer quality on employing PTFE reaction vessels.

3.3.2 Diazonium Salts

Aryldiazonium salts have been used for the direct grafting of aryl groups onto hydrogen-terminated silicon surfaces.^{92–94} These reactions form a special case, and show that solution reactions and surface reactions may have very different outcomes. Reactions with the silicon surface lead to hydrosilylation products, whereas solution reactions with silanes generally lead to substitution of a silicon-bound hydrogen with the counterion of the diazonium salt (Figure 17).⁹⁵ The reaction most likely proceeds via a one-electron reduction of the aryldiazonium cation, yielding an aryl radical and N₂. The

difference between surface reactions and reactions with silanes lies in nature and fate of the electron donor. In solution, electron donation by the silane leads to the formation of a silyl radical cation, which is attacked by the counterion of the diazonium salt. The dissociated hydrogen atom subsequently combines with the aryl radical (Figure 17a).

In contrast, electron donation from the surface leaves a hole that is highly delocalized and is able to migrate into the silicon bulk. The aryl radical picks up a hydrogen atom from the surface, leaving a surface-silicon-centered silyl radical, which reacts with an unreacted aryl radical to form a Si–C bond (Figure 18a). Although direct evidence of this reaction has not been demonstrated, formation of radicals at the surface has been evidenced, by trapping the radicals with alkenes and alkynes, leading to alkyl and alkenyl monolayers (Figure 18b).⁹⁶

Moreover, the electron injection from the silicon bulk into the accepting orbitals in solution is in good agreement with the findings of Hamers and coworkers described above.⁵¹ This is a very elegant example of fabrication of alkyl and alkenyl monolayers at room temperature via controlled radical initiation at the surface. When carboxylate and hydroxyl ω -functionalized alkenes are employed, mainly Si–C bonds are formed. This procedure allows the use of different functional groups without affecting the monolayer quality. Diazonium-initiated attachment occurs fast, as evidenced by the formation of a complete aryl monolayer in 3 hours,⁹⁶ where aryldiazonium salts act as both initiators and reagents (Figure 18b), making this an excellent approach to aryl monolayers. For high-quality alkyl monolayers, other methods may

Figure 17 Reactions of diazonium salts with (a) silane molecules and (b) the silicon surface.

Figure 18 (a) Recombination of surface-centered radicals with abundant aryl radicals leading to the formation of aryl monolayers on silicon. (b) In small amounts, diazonium salts initiate formation of silicon-centered radicals that are trapped by alkenes, leading to the formation of an alkyl monolayer.

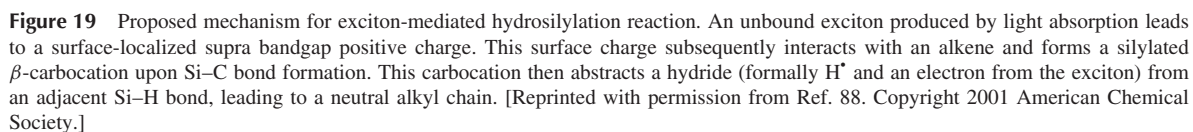

be more suited, given the instability of alkyl diazonium salts, which thus require the involvement of aryl salts that will themselves also show reactivity toward the H-Si surfaces and thus lead to distortions within the formed monolayer. In fact, a parallel can be drawn to the presence of halogen impurities discussed in Section 2.4. Though the aryl attachment is not susceptible to hydrolysis, the disruption of the layer will allow faster penetration of oxygen, resulting in oxidation.

3.3.3 Exciton-Mediated Initiation

Buriak and coworkers found that alkenes attach to porous silicon under irradiation at wavelengths higher than 450 nm.^{64,88} They proposed a mechanism involving excitons, in which electron/hole pairs form near the silicon surface (Figure 19), leading to positive charges on the surface. Nucleophilic attack on a positively charged silicon atom may then result in the formation of a β -carbocation on the attached alkyl chain. Transfer of a hydride from the surface to the β -carbocation yields a neutral alkyl chain. This mechanism, however, does not lead to

a chain reaction, as the attachment of a single chain does not lead to the formation of a new reactive site at the surface.

Zuilhof and coworkers also demonstrated the attachment of alkenes and alkynes onto Si(100)⁹⁰ and Si(111)⁸⁹ by irradiation at 658 nm (white-light reaction). This process is also based on exciton formation, though the charge separation was considered to take place both at the surface and deeper in the silicon bulk. The electronic band structure of silicon would then cause separation of the electron/hole pair, followed by migration of electrons to the silicon bulk. In contrast, the holes move toward the surface, resulting in delocalized radical cations at the silicon surface. Nucleophilic attack of alkenes on these radical cations results in cleavage of a silicon backbond and the formation of a Si-C bond and a β -carbon radical (Figure 20). Hydrogen transfer from the surface to this radical yields a surface-centered radical that propagates the radical chain mechanism.⁸⁹ A recent mechanistic study confirms the reactivity of alkenes and alkynes toward delocalized radical cations, and will be discussed in more detail in Section 4.3.⁹⁷ The studies on monolayer formation at room temperature in the dark

This mild technique, introduced by Zuilhof and coworkers, was shown to result in hexadecenyl monolayers of very high quality (water contact angles $\sim 111^\circ$, and CH_2 stretching vibrations at $\nu_{\text{C-H}} = 2919$ and 2850 cm^{-1}). In order to determine

the origin of this enhancement of the self-assembly process, the difference in reactivity between alkenes and alkynes, as well as the resulting quality of the monolayers, were studied in detail.^{70,98} To this aim, the rate of monolayer formation from both alkenes and alkynes was studied (Figure 21). A clear difference in reactivity of alkenes and alkynes is observed for samples prepared both under visible-light irradiation (Figure 21a) and in the dark (Figure 21b). Under irradiation, 1-hexadecyne monolayers came to completion after 8 hours, whereas the alkene layers were still far from completion (contact angles of $\sim 111^\circ$ and $\sim 100^\circ$).

Figure 21 Static contact angles of 1-hexadecyne ($\circ$) and 1-hexadecene-derived ($\square$) monolayers on H-Si(111) at 20 °C (a) under ambient light, and (b) in the dark, as a function of reaction time. [Both pictures reprinted with permission from Ref. 70. Copyright 2010 American Chemical Society.]

Figure 22 (a) Layer thickness and (b) surface coverages as a function of the number of carbons in alkyne-derived and alkene-derived monolayers, as determined by XPS, ATR, and ellipsometry. [Both pictures reprinted with permission from Ref. 70. Copyright 2010 American Chemical Society.]

respectively).⁷⁰ Comparison of these results to those from the experiments in the dark shows a clear effect of irradiation. Under dark conditions, alkyne-derived monolayers are fully formed (contact angle $\sim 111^\circ$) after 24 hours, whereas the contact angles of the alkene layers do not exceed 97° . These differences in reactivity of the alkenes and alkynes contribute to the differences in nucleophilicity and lower barriers in the hydrogen abstraction reaction at the surface, as will be discussed in more detail in Sections 4.2 and 4.3.

In addition, the structural differences between alkene-derived and alkyne-derived monolayers were studied in detail. A combination of surface analysis techniques (ATR-IR, XPS, ellipsometry, and water

contact angles) was used to determine accurate surface coverages of monolayers prepared from a series of alkenes and alkynes (C12 to C18).⁷⁰ Figure 22 shows the influence of the number of carbons in the chain on the thickness of the monolayer (Figure 22a), and the influence on the surface coverage (Figure 22b). Alkynes lead to thicker layers, indicating that the chains are in a more vertical position than the chains in the alkene layers (tilt angles $22\text{--}35^\circ$ and $37\text{--}40^\circ$ for alkynes and alkenes, respectively). This is in agreement with the observed surface coverages, which are significantly higher for alkynes (55–65% for C12 to C18) as compared to alkenes (50–55% for C12 to C18).

Supportive evidence was found in a modeling study performed by the same group.⁹⁸ Molecular mechanics simulations of the monolayers combined with quantum-chemical calculations showed that alkynes indeed should lead to a higher theoretical surface coverage than alkenes (up to 69% for alkynes vs 50–55% for alkenes) for a variety of reasons. First, the Van der Waals radius of a $\text{H-C}\equiv\text{CH-}$ group is smaller than that of a $\text{-CH}_2\text{-CH}_2\text{-}$. Second, the sp^2 hybridization of the carbon bound to the surface results in a more favorable angle (60° vs surface normal) over a sp^3 hybridized carbon (76° vs surface normal), which lowers the strain energy in the Si–C link. Third, as was shown by G3 calculation, the driving force for Si–C bond formation is $\sim 10 \text{ kcal mol}^{-1}$ higher for 1-alkynes than for 1-alkenes. These factors combined drive monolayer formation for 1-alkynes to a significantly higher degree of surface coverage and correspondingly improved surface properties.

3.3.4 Fluoride-Catalyzed and Neutral Attachment

Though Cerofolini and coworkers support the strong case of radical propagation, they argue that the Si–H bond is too strong for homolytic cleavage at 150°C .⁹⁹ Therefore, they investigated two alternatives: catalytic activity of trace fluoride, and a neutral concerted mechanism, which describe attachment to the silicon surface without initial cleavage of the Si–H bond.⁷⁹ Nucleophilic attack of F^- onto the silicon surface is suggested to result in the formation of pentavalent silicon. This intermediate then releases a hydride that attacks a carbon–carbon double bond, yielding an α -carbanion, which in turn attacks the silicon, substituting fluoride (Figure 23). The result is a neutral alkyl chain as well as a fluoride anion that is available for the next attachment. The proposed alternative mechanism, however, proceeds via a neutral transition state. In a concerted mechanism, the Si–C bond is formed, and the hydrogen is transferred to the alkyl chain. The two mechanisms were found to be indistinguishable in apolar media, whereas the activation energies may indeed be reached at these elevated temperatures.¹⁰⁰ However, both reactions result in a neutral product that does not lead to propagation of the reaction. Neutral attachment and

Figure 23 (a) Fluorine-catalyzed attachment of alkenes to silicon and (b) attachment and hydrogen transfer in a concerted reaction.

fluoride-catalyzed attachment can thus be not important in monolayer formation at ambient and slightly elevated temperatures, as under such conditions the formation of lines and islands of monolayers have been shown, for example, by the aforementioned STM results.⁶⁷ In the case of aldehydes, alkenes, and alkynes, the attachment therefore most likely proceeds mainly via the radical mechanism, as described in Section 3.2.^{89,101}

4 EXPERIMENTAL AND THEORETICAL MODELING STUDIES

In order to better understand the reactions taking place during monolayer formation, modeling studies were undertaken by several research groups. Most theoretical studies make use of a silicon slab or crystal to represent the silicon surface.^{99,102–104} An alternative suitable model is TTMSS, which may provide a good representation of the H–Si(111) surface. Moreover, the chemistry of the TTMSS radical has already been studied in detail,^{45,60,105–107} allowing a clear interpretation of novel reactivity patterns (see **Silanes as Reducing Reagents in Radical Chemistry**). Recently, Fouassier and coworkers extended these reactivity studies to a wide range of alkenes and combined them with density functional theory (DFT) calculations.^{108,109} The calculations of reaction barriers showed good correlation with experimental reaction rates. However, this study was not directed toward monolayer formation on silicon, and the used reagents are not representative of precursors commonly used in monolayer formation experiments. The

experimental setup, however, may be very useful in modeling the radical reaction at the silicon surface.

4.1 Quantum-Chemical Calculations on the Surface Radical Mechanism

While the methods for monolayer fabrication developed into milder and more efficient attachments, the actual kinetics of the reactions at the silicon surface remained until recently largely hidden. In order to gain a better understanding of the propagation mechanism at the silicon surface, Selloni and coworkers conducted a theoretical investigation of the radical chain reaction on silicon surfaces. With first-principles string molecular dynamics (FPSMD), the trajectory of acetylene and ethylene in the addition reaction with Si(111) was modeled, as well as the subsequent hydrogen transfer (Figure 24).^{103,110} A significantly higher addition barrier was found for acetylene than for ethylene (3.5 and 0.9 kcal mol⁻¹ respectively), which seemed to contrast the observed experimental reactivity of the surface, where alkynes display a ninefold higher reactivity.¹¹¹ However, the barrier for hydrogen transfer from the surface to the β -carbon radical is much higher for the attached ethylene (12.5 kcal mol⁻¹) than for acetylene (16.4 kcal mol⁻¹). In fact, the barrier of

hydrogen transfer to the ethylene moiety is even higher than the return barrier for dissociation from the surface (9.7 kcal mol⁻¹). Therefore the authors suggest that ethylene is more likely to desorb from the surface than to accept a hydrogen atom from a neighboring Si–H. This is in agreement with experimental findings of 1-hexene monolayers on silicon, which were shown to dissociate under UHV conditions (no heat or UV required) in an STM setup.¹¹² Although ethylene reacts faster with silyl radicals on the silicon surface, acetylene results in a faster overall reaction, as was also observed in the aforementioned monolayer experiments.¹¹¹ In a follow-up study, the barrier energies of formaldehyde addition (0.7 kcal mol⁻¹) and hydrogen transfer (8.1 kcal mol⁻¹) were calculated. These barriers are lower than those for ethylene or acetylene addition, indicating that reactions of aldehydes are likely to proceed even faster. However, a recent experimental study by Horrocks and coworkers revealed the contrary.¹¹³ Monolayer formation was studied by employing alkene and aldehyde moieties in equimolar amounts in the reaction mixture. The final attachment ratio reflects the rates of alkene and aldehydes addition. The addition of alkenes was found to proceed approximately nine times faster than aldehyde addition. Further modeling studies are therefore required to explain these differences in reactivity.

Figure 25 Competition experiments of TTMSS radical (**8**) with alkene and alkyne. The reactivity ratio is determined by the product ratio of reactions A and B.¹¹⁴

The group of Selloni further demonstrated that stabilization of the β -radical is key to increasing the reactivity of unsaturated carbon–carbon bonds toward silyl radicals.^{102,103} The reaction barriers for the addition of both styrene and phenylacetylene were shown to disappear as a result of the stabilization by the conjugated system. This indicates that addition will proceed rapidly. The barriers for hydrogen abstraction (6.9 and 5.8 kcal mol^{−1} for styrene and phenylacetylene, respectively) are also significantly lower than for the analogous nonconjugated compounds. Furthermore, the authors present the theoretically favorable reaction pathway as strong supportive evidence that the STM-observed styrene lines indeed are formed in a radical reaction. They show that hydrogen transfer between the β -carbon radical and the nearest Si–H site is very likely, and that addition of styrene to a dangling bond is also very favorable. As was discussed in the previous section, the direction of propagation on Si(100) is directed by the surface geometry, resulting in the formation of lines.

UV absorbance above 250 nm, its reactivity cannot be measured directly. Competition reactions involving the silyl radical and two monolayer precursor molecules (e.g., an alkene and an alkyne) resulted in relative reaction rates (Figure 25).

Since terminal alkenes are most commonly used in monolayer fabrication, the reactivity of 1-decene was used for reference (Table 1).^{2,3,50,86} The observed reactivity order of 1-decyne, 1-decene, and 1-undecanal is in good agreement with that obtained from monolayer experiments (aldehyde < alkene < alkyne).^{70,111,113} In addition, the introduction of conjugated bonds has a strong effect on the reactivity. A 10-fold increase in reactivity was observed for phenylacetylene as compared to 1-decene. The predictive potential of these reactivity experiments was demonstrated by the high reactivity of two novel potential precursors for monolayers, namely, hexadeca-3-ene-1-yne and 1,3-hexadecadiyne. The introduction of conjugated bonds leads to a dramatic increase of reactivity (200- and 1400-fold increase for the ene-yne and

4.2 TTMSS as a Model for the Si(111) Surface: Combining Experiment and Theory

Inspired by the mechanistic investigations into the chemistry of the (TMS)₃Si[•] radical (**8**), Zuilhof and coworkers combined the experimental and theoretical results of reactions of silyl radicals with precursors commonly used in monolayer formation¹¹⁴. The objective was to link observed reactivity to a theoretical model to explain and predict the experimental findings. Since the formed β -carbon radical in linear alkenes and alkynes does not display

Table 1 Experimental reactivity ratios (determined at 20 °C) and calculated reaction rates (calculated for 20 °C) for the addition of silyl radicals to monolayer precursors.

Reagent	Reactivity ratio vs 1-decene	Calculated rate (M ^{−1} s ^{−1})
1-Undecanal	0.03	4.2 × 10 ⁴
1-Decene	1.0	6.5 × 10 ⁵
1-Decyne	7.5	3.2 × 10 ⁶
Styrene	—	1.8 × 10 ⁷
Phenylacetylene	91	4.8 × 10 ⁷
Hexadeca-3-ene-1-yne	203	1.1 × 10 ⁸
1,3-Hexadecadiyne	1430	1.0 × 10 ⁹

diyne, respectively), making these compounds very suitable for accelerated monolayer fabrication. Very recently, Rijksen *et al.* have indeed shown that this is the case.¹¹⁵

In order to investigate the rates for the addition reaction, DFT calculations were carried out on a simplified model of **8** (Figure 26). The study showed the importance of taking reaction entropy into account for calculation of the rates, as the rates calculated with inclusion of both enthalpic and entropic effects show a very good correlation with the reactivity ratios (Table 1), while calculations that only account for enthalpic effects do not yield a proper correlation with experimental results. Moreover, the theoretical rates closely resemble experimental rates from literature (8×10^4 , 1×10^5 , and $5 \times 10^7 \text{ s}^{-1}$ for addition of acetone, alkene, and styrene to **8**). The predictive power of the theoretical model was demonstrated by calculation of the rates for the diyne and yne-ene species. The employed models may prove useful in determining which functionalities are compatible, while avoiding undesired side reactions (upside-down attachment).

4.3 Experimental Modeling of Radical Cation Initiation

As discussed already in Section 3, early methods for monolayer formation were based on a substantial

input of energy in order to directly cleave Si–H bonds at the silicon surface. However, the success of new mild procedures shows that there must be another mechanism that coincides with direct cleavage of Si–H bonds. Section 3.3 gives a detailed overview of mechanisms proposed to explain mild attachment, which are supported by experimental findings. Recently, our group reported an experimental kinetics study on the reactivity of silyl radical cations, demonstrating the feasibility of radical cation initiation.⁹⁷ The molecules used in this study were designed to represent the top layer of the hydrogen-terminated silicon surface (Figure 27).

Silyl radical cations of **7**, **9**, and **10**, were efficiently generated by photoinduced electron transfer using *N*-methyl quinolinium salts (NMQ; 355 nm) and toluene as sensitizer and cosensitizer, respectively.¹¹⁶ These radical cations subsequently were shown to react readily with a variety of nucleophiles regularly used in monolayer fabrication. These experiments showed that alkenes and alkynes react with silyl radical cations with high rates ($k_2 \sim 10^6 \text{ M}^{-1} \text{ s}^{-1}$). This is in line with the initiation of monolayer formation by alkenes and alkynes onto hydrogen-terminated surfaces. However, the significantly higher reactivity of oxygen-centered nucleophiles ($k_2 > 10^7 \text{ M}^{-1} \text{ s}^{-1}$) contrasts with the difference in reactivity of aldehydes compared to alkenes that is observed in monolayer experiments (attachment via the alkene moieties was shown to be

Figure 27 Selection of models used to represent the Si(111) surface (**7**, **9**, and **10**) and the subsequent study of the silyl radical cations. TMS = Si(CH₃)₃. [Reprinted with permission from Ref. 97. Copyright 2011 American Chemical Society.]

Figure 28 (a) Nucleophilic attack of alkene to the Si center of the TTMSS radical cation (**11**), resulting in the substitution of a TMS group and the formation of a β -carbon radical. The Si-H (or Si-D) bond remains intact, which is in line with the secondary KIE of 1.2; (b) β -carbon radical intermediates (like those obtainable via a) abstracting hydrogen from TTMSS (**7**), resulting in the formation of the TTMSS radical.

one order of magnitude more favorable than attachment of aldehydes,¹¹³ whereas carboxylic acids do not attach at all.¹¹⁷ Therefore, it can be concluded that, while the radical cation mechanism properly explains the initiation of the visible-light-induced reaction, the propagation step in the preparation of Si-C-linked monolayers does not involve radical cation but only surface-centered radicals. Furthermore, experiments with deuterium-labeled **9** and **10** (Si-D instead of Si-H) showed a (secondary) kinetic isotope effect (KIE) of 1.2, indicating that

cleavage of the Si-H (or Si-D) bonds does not occur in the rate-limiting step of the initiation, but that nucleophilic attack takes place close to the Si-H site. This was confirmed by analysis of the reaction mixtures of **7**, which showed products of substitution reactions (substitution of a TMS group, see Figure 28a). The presence of hydrosilylation products could contribute predominantly to radical formation by nucleophilic attack to the silyl radicals (Figure 28b) and only in a minor degree to spontaneous dissociation of **11**.

5 FUNCTIONALIZED MONOLAYERS ON SILICON SURFACES

The formation of functional monolayers on silicon surfaces has attracted significant attention over the past decades, since functional surfaces are essential in the development of new biosensors and molecular electronics.^{118–120} The presence of functional molecules on silicon surfaces allows selective binding and detection of target biomolecules.^{9, 121–123} In addition, these functional assemblies provide a way to gain control over surface properties such as wettability, friction, and adhesion.¹²⁴ Incorporation of functional moieties on the surface is, however, far from trivial and often relies on the use of protective groups or a reactive intermediate, to which the desired functional molecules are then coupled. Direct attachment of functionalities onto the silicon surface is not desirable, since side reactions readily take place resulting, for example, in upside-down attachment, drastically affecting packing of the alkyl chains in the monolayer, as discussed in the following sections.

5.1 C–H Bond Activation

The incorporation of functional groups into the silicon surface was initially studied by Chidsey and coworkers.^{125,126} Two strategies were studied, both involving C–H activation of terminal methyl groups in an octadecyl monolayer on Si(111). The first method entails illumination of the octadecyl monolayer at 350 nm for 15 minutes in the presence of 4'-[3-trifluoromethyl-3*H*-diazirin-3-yl]-benzoic acid *N*-hydroxysuccinimide ester (TDBA-OSu), (Figure 29). This aryl-diazirine cross-linker inserts into the carbon–hydrogen bonds of the terminal methyl groups of the octadecyl monolayer through a highly reactive singlet-state carbene intermediate.

This reaction was carried out using carbon tetrachloride as solvent and resulted in a surface with amino-reactive *N*-hydroxysuccinimidyl moieties. Although this method is fast, it leads to rather ill-defined structures on the surface. Moreover, only low surface coverages of amino-reactive groups are achieved (approximately 10%) and, as a result, the surfaces remain hydrophobic, affecting further functionalizations. However, this route allowed

Figure 29 Functionalization of octadecyl monolayers on silicon through C–H bond activation, followed by (a) amide and (b) sulfonamide formation. [Reprinted with permission from Ref. 2. Copyright 2002 American Chemical Society.]

Figure 30 Contact-mode AFM height and friction images of a patterned hexadecylated silicon surface. Two circles show monolayer oxidation (-6 V bias at a pixel duration of 2.5 ms), and section profiles are along the arrow above the height images. All patterns were obtained with a resolution of ~ 205 pixels/ μm . [Reprinted with permission from Ref. 128. Copyright 2009 American Chemical Society.]

the successful immobilization of amino-functional biomolecules, such as amino-modified DNA, making these systems suitable for biological scanning probe microscopy (SPM)^{123,126,127}; further improvements on the coverage may be feasible.

Alternatively, a gas-phase free-radical chlorosulfonation reaction was employed to introduce *in situ* highly reactive sulfonylchloride groups onto the octadecyl monolayer by irradiating the surface with 350 nm UV light with chlorine gas in sulfur dioxide. Subsequent reaction with primary amines leads to sulfonamide formation, Figure 29b. This route also results in less disordered amino-modified monolayers than aminopropyltriethoxysilane-based organic films on silicon oxide surfaces. Another advantage of this approach is that the density of sulfonylchloride groups can be controlled by irradiation time, while the conjugation reaction depends on amine concentration and reaction time, allowing for ample control over the surface coverage. The amine-terminated alkyl monolayers obtained after reaction of the sulfonylchloride groups with ethylenediamine provide a facile route to a wide range of heterobifunctional cross-linkers such as benzoylbenzoic acid and *N*-hydroxysuccinimide or direct conjugation of amino-functional biomolecules. Oxidation of terminal methyl groups present on hexadecyl monolayers on Si(111) was recently studied by Zuilhof,

Schubert, and coworkers as a functionalization method.¹²⁸ Densely packed hexadecyl monolayers were locally oxidized using an electrically biased Pt-coated atomic force microscopy (AFM) probe in contact mode. The oxidation behavior was studied as a function of the applied voltage. At low voltages, these monolayers remained unchanged; however, upon increasing the bias voltage, oxidation of the terminal methyl groups occurred, resulting in carboxylic acid moieties. Depending on the voltage employed, as well as the length of the oxidation pulse, a highly controlled partial to complete degradation of the monolayer was achieved, with the concomitant control over the oxidation of the underlying silicon (partial monolayer degradation to yield (among others) carboxylic acid moieties does not lead to surface oxidation yet). Figure 30 shows the contact-mode height and friction images in both directions (trace and retrace) obtained after local probe oxidation of the hexadecyl monolayer.

This method allows even milder local probe oxidations using labile functional groups that are oxidized already at very low bias voltages (e.g., NHS moieties, discussed in the following section). While this process is carried out on the microscale, plasma treatment of alkyl monolayers on silicon gives access to functionality over much larger areas. Hexadecyl monolayers on Si(111) or Si(100)

Figure 31 Schematic representation of the surface reactions during plasma treatment of alkyl monolayers on silicon. [Reprinted with permission from Ref. 129. Copyright 2010 American Chemical Society.]

underwent short plasma treatments (1–3 seconds), which resulted in oxidation of the terminal methyl groups into hydroxyl, aldehydes, and carboxylate functionalities, Figure 31.¹²⁹ Importantly, on Si(111) substrates this did not damage the underlying oxide-free silicon as evidenced by the C 1s and Si 2p signals in XPS narrow-scan analysis. After 1 second of oxidation, C=O bonds represent a significant part of the surface functionalities, in the form of aldehydes groups. Oxidation of the silicon substrate was indeed observed for Si(100) surfaces. After 3 seconds of plasma treatment, 5% of the total Si 2p signal corresponds to SiO₂. Carbon atoms with a single bond to oxygen (C–O) are mostly formed during plasma treatment. This was further evidenced by reacting these monolayers with *p*-trifluoromethylbenzylamine (TFBA), resulting in conjugation with 35–40% of the C=O groups introduced by plasma treatment.

Packing of the alkyl monolayers was not significantly affected by the plasma treatment, as observed by IRRAS. Initially, the symmetric and

antisymmetric C–H stretching vibrations of the CH₂ moieties are observed at 2851 and 2920 cm^{−1}, respectively. Upon plasma oxidation, the intensity of these vibrations gradually decreases, while the CH₃ vibration at 2965 cm^{−1} disappears entirely already after 3 seconds of plasma treatment. The underlying alkyl chains retain their initial packing as indicated by the symmetric CH₂ vibration at 2920 cm^{−1}. To demonstrate the reactivity of aldehyde-terminated monolayers (1 second plasma treatment), reaction with cysteamine was carried, resulting in thiol-terminated surfaces. These surfaces were successfully employed in the attachment of gold nanoparticles (Au NPs). In addition, the binding of Au NPs was used to demonstrate the ability of surface patterning using a plasma. To this purpose, a soft contact mask was employed during the plasma treatment, allowing the formation of patterns with micrometer-sized features, as observed by AFM in Figure 32. This novel and facile route gives access to patterning of high-quality functional silicon surfaces.

5.2 Carboxylic Acids

Carboxylic acid-terminated monolayers have proven to be a very useful scaffold for further functionalization of silicon surfaces.^{117,130,131} However, the quality of the corresponding monolayers depends largely on the method employed for their fabrication. Early investigations by Zuilhof, Sudhölter, and coworkers showed that thermal attachment (200 °C, 2 hours) resulted in significant upside-down attachment. According to FTIR studies, these monolayers display poor packing as compared to alkyl monolayers.⁵⁰ On the other hand, when employing photochemical methods ($\lambda = 300$ nm, 3 hours), high-quality monolayers were obtained without significant upside-down attachment.¹³⁰ This suggests that the acid moiety is able to react with surface Si–H at elevated temperatures, whereas it displays a highly diminished reactivity at room temperature. This compatibility of carboxylic acid moieties with the hydrosilylation reaction was further studied by Bowden and coworkers who functionalized the silicon surface with a mixture of 1-octadecene and a fluoro-capped carboxylic acid in the presence of TEMPO (2,2,6,6-tetramethylpiperidine-*N*-oxyl) (see **Nitroxides in Synthetic Radical Chemistry**)

(Figure 33).¹¹⁷ The thus obtained surfaces were characterized by XPS and IR spectroscopy. The silicon surface did not oxidize, since no signal was observed at the 101–104 eV region in the Si 2p narrow scan.¹³² In addition, the F 1s narrow scan did not display any signals in the 684–694 eV region, indicating the absence of fluorine atoms, which confirms the limited reactivity of acid moieties toward silyl radicals. Chazalviel and coworkers studied the preparation of mixed monolayers employing photochemical methods ($\lambda = 312$ nm) with 1-alkenes and acid-terminated 1-alkenes. A drawback of this method is the use of numerous rinsing steps with hot acetic acid to remove physisorbed carboxylic acid molecules from the silicon surface.¹³³

5.3 Esters: Hydrolysis, Reduction, and Cleavage

As discussed in the previous section, direct attachment of carboxylic acids during hydrosilylation of the silicon surface is problematic because of the formation of silyl esters on the silicon surface.^{50,56,134,135} Instead, the use of 1-alkenes bearing ester moieties such as methyl and propyl

Figure 33 (a) TEMPO-initiated monolayer formation of 1-octadecene and fluorine-capped carboxylic acid resulting solely in the formation of octadecyl layers. (b) No attachment of the carboxylic acids was observed with STM (no fluorine signal in the 684–694 eV region).¹¹⁷

Figure 34 Attachment of 10-undecenyl ester on Si(100) surfaces and formation of acid-terminated monolayers on silicon after hydrolysis.⁵⁰

esters of 10-undecylenic acid has been successfully employed in the formation of monolayers on silicon; subsequent hydrolysis of the esters yielded carboxylic acid-functionalized silicon surfaces, Figure 34.⁵⁰

These ester-terminated monolayers on Si(100) were prepared under thermal conditions (200 °C). The resulting silicon monolayers are well ordered as demonstrated by the antisymmetric and symmetric methylene stretching vibrations in the FTIR spectra (for methyl ester-terminated monolayers: ν_a 2923 cm^{-1} , ν_s 2854 cm^{-1} , and for propyl ester-terminated monolayers: ν_a 2920 cm^{-1} , ν_s 2850 cm^{-1}). The ester moieties do not significantly affect packing of the monolayers. Subsequent hydrolysis of the ester groups led to the formation of acid-terminated monolayers (Figure 34). It may be desirable to use acidic conditions, since strongly alkaline solutions may damage the silicon surface. Acetate-functionalized monolayers on Si(100) have been studied as well. These monolayers were

prepared from 10-undecylenyl acetate employing thermal conditions (Figure 35).⁵⁰ A close packing of the alkyl chains in the monolayer was observed by FTIR spectroscopy. Hydrolysis of these surfaces was foreseen to provide a route to alcohol-terminated surfaces. However, under acidic conditions the acetate moieties were not hydrolyzed, most likely due to inaccessibility of the esters due to steric hindrance. Use of LiAlH_4 , however, conveniently yielded hydroxyl-terminated monolayers.

In addition to these studies, Boukherroub and Wayner investigated the modification of Si(111) surfaces with ethyl undecylenate employing UV irradiation.¹³⁶ Several reactions on the ester moieties using standard chemical and solid-phase chemical procedures were performed to generate functional silicon surfaces (Figure 36). For example, alcohol-terminated monolayers are obtained after reduction of the ester moieties with NaBH_4 , while reaction with an alkyl Grignard reagent gives a tertiary alcohol that can be acylated with acetyl

Figure 35 Attachment of 10-undecenyl acetate on Si(100) surfaces and subsequent reduction to provide alcohol-terminated silicon surfaces.⁵⁰

Figure 36 Modification and reactivity of 10-undecenyl ester-derived monolayers on Si(100) and Si(111) surfaces. Formation of alcohol (b, c) and acid-terminated monolayers (d) and subsequent immobilization of biomolecules (e) using conventional solid-phase amide coupling protocols.¹³⁶

chloride. Finally, hydrolysis of the ester leads to a carboxylic acid-terminated surface that could be coupled to a protected amino acid (glycine methyl ester) using a standard solid-phase amide coupling protocol. The surface density of the ester function can be controlled by dilution of the reacting ester with a long-chain alkene. This has the beneficial effects of minimizing the disruption of the alkyl chain packing in the monolayers and avoiding steric blocking of the ester group.

5.4 Active Esters

Ester and amide linkages are the most frequently employed groups for the conjugation of functional

molecules onto surfaces. As described previously, the ester groups present in an alkyl monolayer are easily hydrolyzed, giving access to alcohols and carboxylic acid functionalities. Carboxylic acid-terminated monolayers may further react with alcohols or amines to form esters or amides, respectively. These reactions are of great interest, because they facilitate the attachment of biomolecules such as proteins, peptides, antibodies, and DNA.^{137,138} However, activation of the carboxylic acid moieties is required. In general, acid-terminated surfaces are activated by carbodiimide reagents, such as 1-ethyl-3-(3-(dimethylaminopropyl)-carbodiimide (EDC) or *N,N'*-dicyclohexylcarbodiimide (DCC) to form a reactive *O*-acylurea intermediate. Upon reaction

Figure 37 Activation of acid-terminated surfaces employing carbodiimide (EDC) reagents and alternative reaction pathways.

with amines, stable amide bonds are formed, Figure 37.^{139,140} These reactions are often carried out in organic solvents, but aqueous solutions are also suitable. Hydrolysis of the *O*-acylurea intermediate may, however, take place in water, limiting the efficiency of conjugation. Alternatively, *N*-hydroxysuccinimide (NHS) has been employed to activate acid moieties. In contrast to the *O*-acylurea intermediate resulting from carbodiimide activation, an NHS ester is formed. These NHS esters are very reactive toward amines and much less prone to hydrolysis than the carbodiimide esters.

The activation of acid-terminated monolayers using NHS/EDC chemistry on silicon, initially introduced by Boukherroub and coworkers,¹⁴¹ is widely employed as a common platform for the *in situ* attachment of amines, so as to obtain functional monolayers on silicon.^{131,142–144} Similarly, several approaches have been developed for the formation of NHS-activated silicon surfaces.^{50,145,146} Many of these procedures rely on the use of ω -ester or ω -acid-terminated 1-alkenes/1-alkynes, requiring several steps and rather harsh conditions that affect the monolayer quality, either after the hydrolysis step (for ester-terminated 1-alkene/1-alkyne monolayers) or due to upside-down attachments (in the case of acid-terminated 1-alkene/1-alkyne),^{142,147} although recently direct photochemical attachment of undecylenic acid was reported to proceed without upside-down attachment.¹³³ The use of photochemical methods enables the direct attachment of NHS esters onto silicon in a one-step reaction by irradiation of the silicon surface immersed in

ω -NHS-functionalized 1-alkene. Although irradiation with 254 nm^{138,148,149} leads to the formation of NHS-activated silicon surfaces, partial decomposition of the NHS-ester-terminated monolayer (30%) and formation of SiO₂ take place, linked to the photoreactivity of the NHS moiety under these circumstances. Recently, the mild and quantitative preparation of NHS-ester functionalized monolayers on silicon surfaces using mild photochemical methods (447 nm) was reported.¹⁵⁰ This method offers an alternative to prepare well-defined mixed monolayers from NHS-functionalized 1-alkene and 1-alkynes at room temperature. Under these conditions, no degradation of the NHS-ester moieties was detected. Further functionalization of the resulting surfaces with a variety of primary amines, as well as with biotin hydrazide, was investigated (Figure 38).

Apart from the attachment of small-molecule amines, NHS esters have been used for immobilization of substituted hydrazide derivatives and even in the covalent coupling of antibodies.¹⁵¹ This method is often applied to the immobilization of proteins, including native proteins, since no additional coupling reagents are required, and the conjugation proceeds in a single step. Achieving high conversion remains an issue however, due to hydrolysis of the NHS esters. Very recently, Sam *et al.*¹⁵² reported on the activation of acid-terminated monolayers via the NHS/EDC route on porous silicon (Figure 39). In these studies, infrared spectroscopy was used to investigate the formation of succinimidyl ester-terminated chains by varying the EDC and NHS concentrations in order to avoid by-products.

Figure 38 Schematic representation of (a) the formation of a mixed monolayer terminated with NHS-ester moieties, and the subsequent substitution of the NHS-ester moiety by (b) *p*-trifluoromethyl benzylamine (TFBA) or (c) biotin hydrazide. Figure 39 Schematic representation of activation reactions at the surface. Interaction between acid-terminated moieties and EDC, forming the *O*-acylurea intermediate (1) and subsequent reaction paths (2–5) for the experimentally detected products (succinimidyl ester, anhydride, urea). The kinetic competition between the various paths determines the final surface composition. [Reprinted with permission from Ref. 152. Copyright 2010 American Chemical Society.]

Equimolar mixing of EDC and NHS in a range of 5 mM was found to be optimal to achieve high conversions. These results are explained in terms of kinetic competition between different reaction pathways, taking into account that sites where NHS adsorbs at the surface become inactive. The applicability of these findings to flat hydrogenated silicon surfaces remains to be demonstrated.

Several alternative strategies have been reported toward activation of acid-terminated monolayers on silicon. For instance, an anhydride-terminated monolayer was obtained after reaction of the terminal acid moieties present in the monolayer with trifluoroacetic anhydride, in the presence of triethylamine.¹¹⁷ These surfaces were further reacted with allylamine in order to yield alkene moieties available for further reactions. Yet another approach relies on the covalent attachment of protected semicarbazide-functionalized alkenes on Si(111) surfaces via photochemical methods (254 nm, 2 hours), as depicted in Figure 40a.¹⁵³

Successful covalent binding of the organic layer onto the silicon surface was demonstrated by XPS and FTIR spectroscopy. However, the silicon surface did not remain oxide-free, especially after the acidic treatment to remove the protecting groups of the semicarbazide moieties. The deprotected semicarbazide-terminated monolayer was then further reacted with peptides bearing a glyoxylyl group for site-specific R-oxo semicarbazone ligation, Figure 40b. Successful peptide immobilization was confirmed by AFM and fluorescence experiments.

5.5 Acid Fluoride Monolayers

A highly useful functionalization of oxide-free silicon surfaces using acid fluoride-terminated alkynes was recently investigated.¹⁵⁴ The acid fluoride functionality is stable under ambient conditions, but reacts readily with strong nucleophiles (amines and anionic nucleophiles). In addition, acid fluoride-terminated monolayers do not form dimeric structures, since hydrogen-bonding interactions do not occur, which prevents extensive washing steps as required for carboxylic acid-containing alkenes/alkynes. These $\text{C}(=\text{O})\text{--F}$ terminated monolayers were prepared from 10-undecynoyl fluoride on oxide-free Si(111) under mild conditions (80 °C,

Figure 40 Schematic representation of (a) the functionalization of silicon surfaces with semicarbazide groups and (b) immobilization with different peptides. [Reprinted with permission from Ref. 153. Copyright 2005 American Chemical Society.]

16 hours; Figure 41). These surfaces remain oxide-free as indicated by the Si 2p narrow scan, in which no signals are observed in the 101–104 eV region. The terminal alkyne functionality of 10-undecynoyl fluoride reacts with H-Si under mild conditions and yields stable $\text{Si-C}\equiv\text{C}$ bonds on Si(111) that are known to inhibit the oxidation of the underlying Si substrate.^{43,69} The ellipsometric layer thickness of 12 Å is consistent with the length of the molecule, and the expected tilt angle of 30–35° with respect to the surface normal confirms the formation of the monolayer. Upside-down attachment are excluded as indicated by ATR-IR, which showed the double-bond stretching vibration of the $\text{Si-C}\equiv\text{C}$ moiety ($\nu_{\text{C}\equiv\text{C}}$ 1603 cm^{-1}) and CH_2 stretching vibrations, which indicate a high-quality packing that is rare for functionalized surfaces, whereas the more easily visible alkyne C-H stretch (expected around $\nu_{\text{C-H}}$ = 3309 cm^{-1}) remained

Figure 41 Schematic representation of the procedure used for μ CP on oxide-free silicon via highly reactive acid fluoride-functionalized monolayers. [L. Scheres, B. Klingebiel, J. ter Maat, M. Giesbers, H. de Jong, N. Hartmann, H. Zuilhof: Micro- and Nanopatterning of Functional Organic Monolayers on Oxide-Free Silicon by Laser-Induced Photothermal Desorption. *Small*. 2010, **6**, 1918–1926. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.]

absent. These acid fluoride-terminated monolayers were also employed as a reactive platform for further functionalization and patterning with primary amines. The high efficiency of amide formation was shown by quantitative amide formation upon application of reactive microcontact printing (μ CP) with a flat poly(dimethoxy silane) (PDMS) stamp (20 seconds) that is indistinguishable from surfaces that were immersed in a solution of *N*-decylamine (1 hours). Both surfaces showed an increase of water contact angle from 83° (acid fluoride layer) to 104°, which is indicative of a methyl-terminated layer. Furthermore, the layer thickness increased in both cases from 12 to 26 Å. ATR-IR showed complete conversion of acid fluorides (complete disappearance of acid fluoride absorption at 1843 cm⁻¹ and the appearance of the amide N–H stretch at 3313 cm⁻¹). The stability of the resulting *N*-hexadecylamide-terminated monolayers in water was investigated by XPS, which displays as most

characteristic feature the lack of oxide formation, even after amide formation (no traces of SiO₂ at the surface around 102 eV). The high reactivity toward amines makes acid fluoride-terminated monolayers excellent platforms for reactive μ CP, while the high selectivity of the amide formation makes them excellent intermediates for introducing a broad range of functionalities on oxide-free silicon surfaces, including complex biomolecules, such as fluorescently labeled oligo-DNA on oxide-free silicon, which is still accessible for hybridization.¹⁵⁴

For more information regarding μ CP, the reader is directed to the work of Zhu and coworkers (μ CP of alcohols on Si–Cl surfaces),¹⁵⁵ that of Mizuno and Buriak (μ CP of 1-octadecyne directly on Si(111) and Si(100) by use of catalyst-impregnated stamps),¹⁵⁶ and the work of Toone and coworkers (catalytic conversion of terminal groups on the monolayer by chemically modified stamps).^{53,157}

5.6 Click Chemistry

Owing to the relatively sensitive nature of silicon surfaces, the wide range of desirable functionalizations requires versatile reactions that proceed under mild conditions. Hence, in addition to, for example, the amide-forming reactions from NHS esters or acid fluorides (see above), click reactions have attracted considerable attention for orthogonal and site-selective immobilization of functional moieties.¹⁵⁸ Click reactions are identified by the mild reaction conditions needed, their high chemo- and regioselectivity, and their efficiency.^{158,159} Gooding and coworkers prepared alkyne-terminated monolayers on Si(100) through thermal addition of 1,9-nonadiyne. Subsequently, the Cu-catalyzed azide-alkyne cycloaddition was employed to attach a variety of functional azides onto these monolayers.^{160,161} Very robust oxide-free modified silicon surfaces were produced via the hydrosilylation reaction. Moreover, these surfaces are stable to allow the preparation of redox assemblies for aqueous environments and antifouling surfaces.^{161,162}

The radical addition reaction of thiols to alkenes or alkynes has recently emerged as an elegant and appealing alternative coupling reaction (see **Radical Thiol-X Click Chemistry**). Very mild reaction conditions, the absence of a metal catalyst, and the ready availability of thiol-functional (bio)molecules are distinctive features of this coupling chemistry.^{159,163,164} In addition, these radical reactions have been used as an efficient strategy toward immobilization and patterning of biomolecules on inorganic substrates such as gold, glass, and silicon.^{159,162,165} For example, Bertin and Schlaad used thiol-ene chemistry as a method to rapidly functionalize glass substrates with polymers.¹⁶⁶ Dendrimeric and polymeric approaches have been reported, demonstrating both thiol-ene and thiol-yne chemistry. Waldmann and coworkers, for example, used polyamidoamine dendrimers attached covalently to silicon oxide surfaces to develop a new method for the site-specific immobilization and patterning of proteins.^{167,168} Patton and coworkers used silicon substrates functionalized with silanes to generate a library of polyfunctional, patterned, and multicomponent polymer brush surfaces.¹⁶⁹ Recently, Ravoo and coworkers reported the immobilization of functional thiols on

alkene- and alkyne-terminated SAMs on silicon oxide substrates by photochemical μ CP.¹⁷⁰ Although these strategies are not specific for oxide-free silicon surfaces, the versatility of the employed coupling strategies allows their easy extension to these surfaces. This was shown, for example, by Buriak and coworkers who used thiol-ene chemistry for the layer-by-layer assembly of α,ω -dithiols and α,ω -diene molecules on oxide-free silicon, silicon oxide, and germanium surfaces.¹⁷⁰ The Si(100) surfaces were modified using photochemical methods (254 nm, 3 hours) by reacting the hydrogen-terminated silicon surface with the desired α,ω -diene (i.e., 1,7-octadiene, 1,11-dodecadiene). The alkene-terminated monolayers thus obtained were immersed in neat α,ω -dithiols, and after UV irradiation for 0.5 hours, thiol-terminated monolayers were generated. Subsequent reaction of these silicon surfaces with α,ω -dienes led to the formation of alkene-terminated monolayers, and this procedure was continued until the desired number of layers was reached, Figure 42. This layer-by-layer approach provides an interesting platform for growing covalently bound films of controlled thickness onto oxide-free silicon.

Recently, Zuilhof and coworkers reported on a versatile approach employing thiol-ene click chemistry as a versatile, efficient, and patternable route to functionalize silicon surfaces under ambient atmosphere without the introduction of silicon oxide.¹⁷¹ In these studies, alkene-terminated monolayers on oxide-free Si(111) were obtained after reaction of hydrogen-terminated Si(111) with neat 1,13-tetradecadiene under thermal conditions (80 °C, 16 hours). The alkene-terminated monolayers were further exposed to 365 nm light in the presence of different functional thiols and 2,2-dimethoxy-2-phenylacetophenone (DMPA), which acted as a photoinitiator (Figure 43). This led to a wide range of functionalized surfaces, which in all cases displayed a high surface coverage (45–75%; typically limited by the steric bulk of the functional group with respect to the alkene chains), while the silicon surfaces did not undergo any discernable oxidation.

In addition, μ CP of thioglycolic acid onto an alkene-terminated monolayer was investigated. A PDMS stamp with 10- μ m pillar-like features was covered with a mixture of thioglycolic acid and

Figure 42 (a) Schematic representation of the covalent molecular layer deposition assembly of a thiol-ene multilayer, (b) chemical structure of the multilayer assembly, and (c) dienes and dithiols employed in this study. [Reprinted with permission from Ref. 170. Copyright 2009 American Chemical Society.]

DMPA in ethanol, subsequently brought into contact with the alkene-functional silicon substrate, and next the surface was irradiated through the stamp for 5 minutes. After thorough cleaning of the substrate, the surface displayed a 10- μm sphere pattern in the AFM phase image, confirming successful transfer of the pattern, as shown in Figure 43c.¹⁷¹ This further demonstrates that thiol-ene chemistry provides an efficient method for metal-free light-induced patterning onto silicon.(c)

6 PERSPECTIVES

The rapidly development of novel approaches to form covalently attached monolayers on silicon surfaces parallels the deepening insights into silyl radical chemistry. The high stability of Si-C bonds, in combination with the versatile chemistry available for the functionalization of monolayers, makes these systems ideal platforms for electronic

and sensory devices. This section outlines the currently unresolved “hot” topics in this area.

Since the pioneering research in the early 1990s, monolayer fabrication has seen major developments. Starting from experiments using relatively harsh reaction conditions (temperatures $>200^\circ\text{C}$),^{49,56} methods progressed into much milder methods for the generation of surface-centered silyl radicals. Si-H bonds were also shown to cleave under UV irradiation,^{43,78,83} and eventually monolayer formation was demonstrated to occur without the direct cleavage of these bonds (white-light method and attachment in the dark).^{64,69,88–90} These increasingly milder methods have resulted in the direct attachment of sensitive molecules, such as complex sugars and peptides, that would otherwise degrade.¹⁷² At this moment, experimentalists have a repertoire of mild methods and techniques available.^{2–4} Depending on the desired properties, ease of use, and availability of precursors, several options exist for the fabrication of monolayers on silicon.

Figure 43 (a) Schematic representation of functionalization of silicon surfaces using thiol–ene chemistry; (b) Thiols employed in surface functionalization, with corresponding surface coverages; (c) AFM phase image of the patterned silicon monolayer with thioglycolic acid. [M. A. Caipa Campos, J. M. J. Paulusse, H. Zuilhof, *Chem. Commun.* 2010, **46**, 5512–5514—Reproduced by permission of The Royal Society of Chemistry. <http://dx.doi.org/10.1039/C0CC01264E>.]

A major challenge, however, still lies in speeding up monolayer formation. Where typical formation of SAMs from thiols on gold using stamps takes minutes,¹⁷³ attachment onto silicon is still takes hours. Experiments have shown that up to 90% of the layer is formed within minutes; yet filling up the remaining holes (and thus completing the layer) is a slow process.^{67,174} Looking from a radical chemistry perspective, basically there are two approaches to achieve this speedup. The first approach is to change reaction conditions in order to initiate more dangling bonds at the silicon surface. Radical addition and the subsequent hydrogen transfer have been shown to be efficient reactions for covalent attachment of precursors. In this respect, addition of radical initiators and/or catalysts may prove valuable in increasing the reaction rates, as long as no undesirable side reactions take place. Additionally, irradiation (UV or visible light) possibly assisted by electronic modification of the surface properties

(bias voltages) may also catalyze the formation of surface-centered radicals.

A promising second approach to the speedup may lie in the modification of the precursors. An enhanced reactivity in both the addition and hydrogen-transfer steps may lead to larger islands and longer lines, depending on the surface (Si(111) and Si(100), respectively).^{114,115} Moreover, recent studies show that modification of these precursors—in order to reduce the number of close contacts near the surface—also contributes to higher surface coverages and increased packing of the monolayers.⁹⁸

Another “hot” topic is the functionalization of monolayers. With the advent of efficient coupling chemistry, also new moieties are readily introduced in the monolayers. Functionality of these layers has progressed from aldehydes and acids to azides and alkenes, which can be used in “click” chemistry (alkyne–azide, thiol–ene, etc.) for the attachment of more complex molecules. However,

the ever-increasing demand for high-quality monolayers on oxide-free silicon requires side reactions of functional moieties to be reduced to an absolute minimum, as indicated, for example, by the attachment of ω -aldehyde functionalized alkenes to Si(111).¹¹³ Since aldehydes are also reactive toward silyl radicals, up to 10% of the precursors attaches via this moiety instead of the desired attachment via the alkene. For aldehyde-functionalized alkynes, however, this ratio is expected to further shift in favor of the alkyne attachment. In general, alkyne-derived Si–C-linked monolayers display superior linking properties as compared to alkene-based monolayers in terms of packing density,^{70,98} rate of formation,^{69,70,97,114} and stability toward oxidation,¹²³ and alkyne precursors are thus expected to be the basis of novel functional monolayers on silicon surfaces.

Persistent and Stable Silyl Radicals

Boris Tumanskii, Miriam Karni and Yitzhak Apeloig

Schulich Faculty of Chemistry and the Lise Meitner-Minerva Center for Computational Quantum Chemistry, Technion-Israel Institute of Technology, Haifa, Israel

1 INTRODUCTION

Silyl radicals are reactive intermediates that play an important role in many fields of chemistry. For recent reviews see Refs 1–7. For example, silyl radicals efficiently abstract halogen atoms from organic halides, and thus serve as reducing agents in organic synthesis (Scheme 1a)^{3,4,7}; they are also efficient photoinitiators of polymerization (see **Overview of Radical Initiation**)⁸ and are used as catalysts in cyclotrimerization of acetylenes.⁹ Silyl radicals are also intermediates in the synthesis and photodegradation of polysilanes, an important class of polymers^{10,11} (Scheme 1b).

Silyl radicals are often generated on silicon surfaces¹²—one of the technologically most important materials in the electronic industry. For example, significant recent attention is directed toward the synthesis of organic monolayers on silicon surfaces which can be modified for specific technological requirements,^{12,13} as demonstrated in Scheme 2 for H–Si(111) surfaces (see **Silicon Radical Surface Chemistry**). Such surfaces undergo radical-activated reactions involving silyl radicals with a variety of terminal olefins to yield densely packed monolayers, which can be modified for specific requirements (Scheme 2).¹³

In view of this broad interest and the numerous applications of silyl radicals in general and of polysilyl radicals in particular, knowledge of their fundamental properties and ways to control their reactivity is very important.

Simple aliphatic carbon-centered¹⁴ and silicon-centered radicals^{15,16} are in general highly reactive intermediates and have very short lifetimes. For example, $\text{MeH}_2\text{Si}^\bullet$, $\text{Me}_2\text{HSi}^\bullet$, and $\text{Me}_3\text{Si}^\bullet$ were observed by electron paramagnetic resonance (EPR) spectroscopy in solution only at low temperature (150–200 K) and their half-lifetimes ($\tau_{1/2}$) are at an estimated range of 0.005–0.01 s.^{15,16} Bulky alkyl, aryl, and silyl substituents reduce the reactivity of simple C-centered radicals prolonging their lifetimes, making them relatively long-lived.^{17,18} Several stable carbon-centered radicals stabilized by conjugation, for example, triarylmethyl, have been isolated.^{19,20} One case of a stable aliphatic silyl-substituted carbon-centered radical lacking resonance stabilization has also been reported.²¹ A stable triarylgermyl radical was recently isolated.²² In contrast, triarylsilyl radicals are not stable enough to be isolated; their half-life times are estimated to be 0.1–1 s (Figure 1).²³

The properties, chemistry, and stability of reactive short-lived silyl radicals have been reviewed.^{3–5} In this review, we concentrate on persistent and stable silyl radicals. The synthesis and isolation of stable silyl radicals and their heavy congeners is fundamentally interesting and opens up many new opportunities. For example, stable radicals can serve as “building blocks” for new materials which may possess a unique combination of magnetic, electrochemical, and photochemical properties. Stable aromatic organic radicals, such as dendritic and polymeric radicals of the triphenylmethyl type, have

Figure 1 Triaryl-substituted group 14 radicals.

1.1 Controlling the Stability of Silyl Radicals

The thermodynamic and kinetic stability of radicals can be controlled by the electronic and steric effects of their substituents.

1.1.1 Thermodynamic Stabilization—Electronic Effects

There is little data, either experimental or theoretical, on the effect of substituents on the stability of silyl radicals. The experimental and theoretical data presented here were gathered from different sources. For experimental data, two main sources were used: (i) the comprehensive NIST database³³ and (ii) *Handbook of Bond Dissociation Energies in Organic Compounds*.³⁴ We have also used experimental data reported in the references that are cited in Table 1. The reported theoretical values are at different levels of calculation, and the reader is referred to the cited original papers given in Table 1 for details.

A measure of the thermodynamic stability of a substituted radical $\text{RH}_2\text{E}^\bullet$ is provided by the E–H bond dissociation energy (BDE) of RH_3E . Substituents that reduce the BDE stabilize the radical, and vice versa. The stabilization energy of $\text{RH}_2\text{E}^\bullet$ relative to $\text{H}_3\text{E}^\bullet$, reflecting the effect of

already found applications as organic magnets²⁴ and as new paramagnetic materials,²⁵ and nitroxyl type radicals have been applied in organic radical polymer batteries (see **Tin Hydrides and Functional Group Transformations**).²⁶ Fullerene-based stable radicals can potentially be used in electron-spin quantum computing,²⁷ and stable silyl radicals can in principle play a similar role.

In this review, the major focus is on persistent and stable silyl radicals, and in particular on stable polysilyl radicals which are the majority in this group. We define a stable radical as one that can be isolated and handled as a pure compound. Radicals that are relatively long-lived and can be observed using conventional spectroscopic methods, but cannot be isolated, are classified as “persistent.”¹⁷ The term “persistent” is of course subjective and we use it for radicals that have a lifetime of several hours or longer.

Readers who are interested in radicals of the heavier congeners of silicon, Ge, Sn, and Pb are referred to Refs 2, 6, and 28–32.

Scheme 2 Silyl radical activated olefination of a H-Si(111) surface.

substituent R, is given by the difference between the E–H BDE in EH_4 and in H_3ER . This value is referred to as the *radical stabilization energy* (RSE) and is determined by isodesmic hydrogen transfer equations (1a) [(1b) for $\text{R}_3\text{E}'$]. The thermodynamic effect of the substituents is attributed to their ability to delocalize the unpaired electron.^{36,38,43,45} The energies of isodesmic equations (1a) and (1b) for $\text{E} = \text{Si}$ and C and $\text{R} = \text{Me}$, Ph (phenyl), Li , SiH_3 , SiMe_3 , F , Cl , Br , and NH_2 are collected in Table 1. Isodesmic equation (2) (Table 1) compares the RSEs of $\text{R}_3\text{Si}'$ relative to those of $\text{R}_3\text{C}'$. The experimental energies of (1) and (2) were derived from E–H BDEs or from relevant heats of formation. A positive value indicates that R is stabilizing, that is, (1), or that $\text{R}_3\text{C}'$ is more stable than $\text{R}_3\text{Si}'$, that is, (2).

Substitution of $\text{H}_3\text{Si}'$ with one methyl group has a small destabilizing effect of 1 kcal mol^{-1} (1a). Three methyl groups destabilize it by $2.9 \text{ kcal mol}^{-1}$.³⁷ A single phenyl substituent does not affect the stability of $\text{H}_3\text{Si}'$, and $\text{Ph}_3\text{Si}'$ is stabilized by circa 3 kcal mol^{-1} relative to $\text{H}_3\text{Si}'$. The electropositive silyl substituent has a significantly larger stabilizing effect, and $(\text{R}_3\text{Si})_3\text{Si}'$ ($\text{R} = \text{H}$, Me) is stabilized by circa $\sim 7\text{--}9 \text{ kcal mol}^{-1}$ relative to $\text{H}_3\text{Si}'$. A β -silyl substitution is calculated to have no effect on the thermodynamic stability of silyl radicals.⁴⁷ The electropositive Li substituent has a large calculated stabilizing effect of 12 kcal mol^{-1} .⁴³ On the other hand, the electronegative fluorine destabilizes the silyl radical and $\text{F}_3\text{Si}'$ is by 11 kcal mol^{-1} (experimental, calculated $6.5\text{--}7.5 \text{ kcal mol}^{-1}$) less stable than $\text{H}_3\text{Si}'$ (Table 1). Chlorine substitution has a small effect on the stability of $\text{H}_3\text{Si}'$, while three bromine substituents stabilize the silyl radical by as much as 6 kcal mol^{-1} (calculated) or 12 kcal mol^{-1} (experiment) (Table 1). The π -donating amino group is slightly destabilizing (Table 1). In summary, the substituent stabilizing effect follows the order [(1a) and (1b), Table 1] Li (strongly stabilizing) $\gg \text{Br} \approx \text{SiR}_3 > \text{phenyl} > \text{Cl} \approx \text{Me} \approx \text{NH}_2 > \text{F}$ (strongly destabilizing).

A comparison of the thermodynamic stability of silyl radicals and the corresponding alkyl radicals (2) is of interest. The parent $\text{H}_3\text{Si}'$ radical is thermodynamically more stable than $\text{H}_3\text{C}'$ by $\sim 13 \text{ kcal mol}^{-1}$ ⁴⁵ (Table 1). However, as the effect of substituents on $\text{H}_3\text{C}'$ and $\text{H}_3\text{Si}'$ is very different (compare (1a) and (1b) for $\text{E} = \text{C}$ and $\text{E} = \text{Si}$, Table 1), the relative stabilities of substituted silyl and methyl radicals change significantly depending on R. For example, three methyl groups stabilize the methyl radical by as much as $9.5 \text{ kcal mol}^{-1}$ ³³ (exp., $6.8 \text{ kcal mol}^{-1}$ calc.,³⁹ Table 1), in contrast to a destabilization of $2\text{--}3 \text{ kcal mol}^{-1}$ of the silyl radical. These opposing substituent effects place $\text{Me}_3\text{C}'$ and $\text{Me}_3\text{Si}'$ at nearly the same thermodynamic stability ((2) for $\text{R} = \text{Me}$ is nearly thermoneutral). Similarly, the π -conjugating phenyl substituents have a significant stabilizing effect of 24 kcal mol^{-1} on the methyl radical and thus $\text{Ph}_3\text{C}'$ is $\sim 8 \text{ kcal mol}^{-1}$ more stable than $\text{Ph}_3\text{Si}'$. The electropositive silyl substituent has a similar stabilizing effect on both silyl and methyl radicals and therefore $(\text{R}_3\text{Si})_3\text{Si}'$ is more stable than $(\text{R}_3\text{Si})_3\text{C}'$ ($\text{R} = \text{H}$, Me) by $\sim 15\text{--}16 \text{ kcal mol}^{-1}$ (Table 1). An amino group has a significant stabilizing effect on a methyl radical but a small destabilizing effect on the analogous silyl radical, and thus $(\text{H}_2\text{N})_3\text{Si}'$ and $(\text{H}_2\text{N})_3\text{C}'$ have similar stability.

1.1.2 Kinetic Stabilization—Steric Effects

Kinetic stabilization of silyl radicals is effectively achieved by the introduction of bulky substituents. For example, $(\text{Me}_3\text{Si})_3\text{Si}'$ has a half-life of $0.1\text{--}1 \text{ s}$, and $(i\text{-Pr}_3\text{Si})_3\text{Si}'$ has a half-life of 3 days.⁴⁸ The use of even larger substituents, such as $t\text{-Bu}_2\text{MeSi}$, has led recently to the isolation and structural characterization of stable silyl radicals and other group-14-centered radicals.^{1,2,28–31,49,50} These large silyl substituents sterically protect the radical center from undergoing typical radical reactions, such as dimerization, hydrogen abstraction, and disproportionation, and prolong their lifetime. For example, $(t\text{-Bu}_2\text{MeSi})_3\text{Si}'$ is stable at room temperature for several years in an inert medium.^{49,50}

Another important factor controlling the lifetime of $\text{R}_3\text{E}'$ is the central atom E.^{5,14–18,23,32,51} The heavier the E atom, the longer is the E–E bond

in the dimer formed by recombination of two R_3E radicals and consequently the larger the substituents required to create sufficient steric repulsion which would inhibit dimerization and thus stabilize kinetically the radical. In R_3C-CR_3 , the C–C distance is 1.5–1.6 Å⁵² and six $R = Me_3Si$ substituents cause steric repulsion, which is large enough to hinder dimerization, making $(Me_3Si)_3C^\bullet$ persistent with a lifetime of several days at 298 K.^{17,18} In sharp contrast, the analogous Si-centered radical $(Me_3Si)_3Si^\bullet$, which is thermodynamically more stable than $(Me_3Si)_3C^\bullet$ (see Table 1, Section 1.1.1), is highly reactive ($\tau_{1/2}$ of 0.1–1 s at 298 K).^{5,16} This large difference in the lifetimes between $(Me_3Si)_3C^\bullet$ and $(Me_3Si)_3Si^\bullet$ is due primarily to the fact that the Si–Si bond distance in the corresponding dimer (2.4 Å),⁵³ is much longer than that of a C–C bond and therefore the Me_3Si substituents are not large enough to suppress the dimerization of $(Me_3Si)_3Si^\bullet$. Thus, the high kinetic stability of $(Me_3Si)_3C^\bullet$ imposed by the substituents' steric effects overrides its lower inherent thermodynamic stability compared with that of $(Me_3Si)_3Si^\bullet$, as well as the fact that the C–C bond is much stronger than a Si–Si bond (90.2 kcal mol^{−1} for H_3C-CH_3 vs 76.7 kcal mol^{−1} for $H_3Si-SiH_3$ ⁵²). The relationship between the dissociation energy of the central Si–Si bond in $R_3Si-SiR_3$ and the kinetic stability of the corresponding $R_3Si^\bullet$ radicals is discussed in more detail in Section 2.4.1.

1.2 Structure

The methyl radical, $H_3C^\bullet$, is planar.⁵⁴ In contrast, $H_3Si^\bullet$ has a pyramidal C_{3v} structure (where the sum of the bond angles around the radical center ($\Sigma\theta$) is 332.6°) and the inversion barrier is 5.3 kcal mol^{−1}.^{55,56} $Me_3Si^\bullet$ is slightly more pyramidal than $H_3Si^\bullet$ ($\Sigma\theta = 331.1^\circ$), but its inversion barrier is significantly higher, 12.1 kcal mol^{−1} (Y. Apeloig, *et al.*, unpublished results). Calculations predict that α -trisubstituted silyl radicals $R_3Si^\bullet$ ($R = H_3C, H_2N, OH, F, H_3Si, H_2P, HS, Cl$) are all pyramidal at the silicon radical center (Figure 2) (Y. Apeloig, *et al.*, unpublished results).⁵⁷ The degree of pyramidality is larger for substituents that possess lone-pair electrons ($\Sigma\theta$ of 321–327°) (Y. Apeloig, *et al.*, unpublished results see also Ref. 57). On the other hand, silyl substituents decrease the degree of pyramidality; for example, in $(H_3Si)_3Si^\bullet$ $\Sigma\theta = 348^\circ$

Figure 2 Calculated (UB3LYP/6-31+G(d)) degree of pyramidality $\Sigma\theta$ and inversion barriers (kcal mol^{−1}) of several silyl radicals (Y. Apeloig, *et al.*, unpublished results).

and the inversion barrier is 0.9 kcal mol^{−1} and it decreases to only 0.2 kcal mol^{−1} in $(Me_3Si)_3Si^\bullet$ (Figure 2) (Y. Apeloig, *et al.*, unpublished results). Larger silyl substituents decrease the degree of pyramidality and the inversion barrier even further, and X-ray analysis shows that $(t-Bu_2Me)_3Si^\bullet$ is planar (*vide infra*).⁴⁹

More calculations on the structures and magnetic properties of various silyl radicals are available, and the interested reader is referred to these papers.^{51,57–59} Accurate quantum mechanical calculations of structural and EPR parameters of other free radicals can be found in Refs 60–62.

2 TRIS(SILYL)-SUBSTITUTED SILYL RADICALS

This group of radicals deserves a separate section because they comprise most of the known persistent and stable silyl radicals.

2.1 Methods of Generation

The methods used to generate silyl radicals in general and tris(silyl)silyl radicals in particular, can be divided into three major groups: (i) Methods involving hydrogen abstraction from Si–H bonds (Scheme 3, path (a)); (ii) Si–Si or Si–Hg bond cleavage by photolysis or thermolysis (Scheme 3,

Scheme 3 Generation of silyl radicals by bond cleavage.

Scheme 4 Generation of silyl radicals by one-electron reduction of silylhalides and by one-electron oxidation of metallosilanes.

path (b) and (c), respectively). These methods are usually used to generate reactive or persistent radicals within the cavity of the EPR spectrometer; (iii) Methods involving one-electron reduction of silylhalides or one-electron oxidation of metallosilanes (Scheme 4). These methods allow obtaining radicals in high concentrations, making it possible in some cases to isolate them.

2.1.1 Hydrogen Abstraction

Hydrogen abstraction is the most widely used method for generating silyl radicals. It involves the reaction of silicon hydrides with atoms, radicals, or excited molecules (3).^{3,15,16,50,51}

For example, the reaction of photolytically generated $t\text{-BuO}^\bullet$ with tris- or bis(silyl) substituted silanes was extensively used to produce silyl radicals for organic synthesis and for their study by EPR spectroscopy ((4) and (5), respectively; radical numbers

refer to the radicals given in Tables 2–4).^{3,15,51}

A variety of silyl radicals, shown in Tables 2 and 4, ranging from the short-lived $\text{Me}_3\text{Si}^\bullet$,¹⁵ **1–4**,^{5,16,63} and **16–22**⁵¹ to the persistent ($i\text{-Pr}_3\text{Si}$)₃Si[•] (**7**) radical,⁴⁸ were generated using this method. The main disadvantage of this method is its low yield and therefore in general it cannot be used for the preparative synthesis of stable silyl radicals.

2.1.2 Si–Si Bond Cleavage

A variety of silyl radicals were generated by photolysis or thermolysis of polysilanes.^{47,63,64} For example, the tris(silyl)silyl radicals ($\text{Et}_n\text{Me}_{3-n}\text{Si}$)₃Si[•] ($n = 1–3$) were generated by photolysis of tetrakis(silyl) silanes ($\text{Et}_n\text{Me}_{3-n}\text{Si}$)₄Si and hexakis(silyl) disilanes [($\text{Et}_n\text{Me}_{3-n}\text{Si}$)₃Si]₂ (**6**).⁶³

Photolytic generation of polysilyl radicals from the corresponding dimers is not always a selective processes and it can produce several radicals from a single precursor. For example, photolysis of the polysilane shown in Scheme 5 leads to the formation

Table 2 EPR parameters, stability (at 298 K), and calculated degree of pyramidality of tris(silyl)silyl radicals.

of two radicals: a short-lived radical ($\tau_{1/2} \sim 1$ s) formed by cleavage of the central Si–Si bond and a longer lived persistent radical ($\tau_{1/2} \sim 50$ min) obtained by cleavage of one of the $\text{Me}_3\text{SiMe}_2\text{Si}$ groups (Scheme 5).⁶⁴

2.1.3 Si–Hg Bond Cleavage

Photolysis of silyl-mercury compounds produces silyl radicals with high *selectivity* because only the silicon–mercury bond is cleaved (7).^{47,70,71} This is a major advantage over the photolysis of polysilanes where several fragmentation pathways are competing. Furthermore, the concentration of the silyl radical produced by this method is usually high, producing good quality EPR spectra. Additional advantages are that there is no need to use initiators and the only side-product is metallic mercury which is easily removed. Examples of radicals produced by this method are: **5**, **8**, **25**, and **26** (see Tables 2 and 4).^{65,69,70}

2.1.4 Oxidations and Reductions

One-electron oxidations and reductions are powerful methods for generating persistent and stable radicals in high yield.^{1,6,66,71} The first two silicon-centered radicals that were isolated and characterized by X-ray crystallography **9**⁴⁹ (Figure 3) and **12**⁵⁰ (Table 2) were produced by one-electron oxidation reactions. Sekiguchi and coworkers prepared in 2002 (*t*-Bu₂MeSi)₃Si[•] (**9**) by oxidation of (*t*-Bu₂MeSi)₃SiNa (**8**) and isolated it as air-sensitive yellow needles.⁴⁹ More recently Apeloig and coworkers synthesized by a single-pot

Figure 3 ORTEP diagram of the X-ray molecular structure of (*t*-Bu₂MeSi)₃Si[•] (**9**). [Adapted with permission from Ref. 49. Copyright 2002 American Chemical Society.]

substitution-oxidation reaction the new stable radical **12** (see below).

The persistent (*t*-BuMe₂Si)₃Si[•] (**8**) (Table 2) was generated by Kira and coworkers in 1998 by the oxidation of (*t*-BuMe₂Si)₃SiNa (Scheme 6, path a) with NO⁺BF₄[−] and by the reduction of (*t*-BuMe₂Si)₃SiBr (Scheme 6, path b), as well as by hydrogen abstraction from (*t*-BuMe₂Si)₃SiH (Scheme 6, path c).⁶⁶

An interesting example of the use of one-electron oxidation and reduction reactions to produce the unique cyclotetrasilanyl silyl radical **15** is shown in Scheme 7.^{67,68} Radical **15** was generated from the corresponding cyclotetrasilanylium cation⁷² by reduction with sodium metal or KC₈ in ether and it was isolated as red-purple crystals. Cyclotetrasilanyl radical **15** is the first stable polysilyl

Scheme 6 Synthesis of radical **8** by several methods.

Scheme 7 Synthesis of cyclotetrasilanyl silyl radical **15**.

radical with allylic conjugation as is also clear from its spin-density distribution (Table 2).⁶⁷ Radical **15** can be reduced further by alkali metals to the corresponding silyl anion.⁶⁷ Remarkably, all the reduction–oxidation processes shown in Scheme 7 are reversible.

More recently, a new efficient one-pot method for preparing stable silyl radicals in high yield was developed by Apeloig's group.⁵⁰ Reaction of trichlorosilanes or dichlorosilanes with aggregated nonsolvated bulky trialkylsilyllithiums produces in high yield stable or persistent silyl radicals (**9**).⁵⁰ For example, reaction of trichlorosilane with 3 mole equiv of (*t*-Bu)₂MeSiLi in hexane yields the stable (*t*-Bu₂MeSi)₃Si[•] radical (**9**) in 85% yield after recrystallization.⁵⁰ The previous method, which uses a one-electron oxidation to produce **9** (**8**), consists of four steps and produces radical **9** in a lower yield of 44%.⁴⁹

Several new persistent and stable silyl radicals, such as **10–14** (Table 2) as well as

Ph(*t*-Bu₂MeSi)₂Si[•] (**23**) and Mes(*t*-Bu₂MeSi)₂Si[•] (**24**) (Table 4), were recently synthesized by Apeloig *et al.* using the method in (9) (Y. Apeloig, *et al.*, unpublished results.).⁵⁰

2.2 X-Ray Crystallography of Silyl Radicals

Currently, the X-ray structures of four stable radicals, namely, **9**, **11**, **12**, and the cyclotetrasilanyl silyl radical **15**, have been solved. Radical **9**, whose X-ray molecular structure is shown in Figure 3,⁴⁹ has a trigonal-planar geometry around the Si radical center ($\Sigma\theta = 360^\circ$). Steric effects dictate or contribute to many of the structural details, such as the planarity of the radical center and the clockwise arrangement in the Si1–Si2–Si3–Si4 plane of all methyl substituents at the peripheral Si atoms, thus minimizing the steric repulsion of the bulky *t*-Bu groups. The Si–Si bond length (average 2.42 Å) are slightly longer than the normal values of 2.30–2.40 Å.⁷³

The X-ray molecular structures of radicals **11** and **12** (Y. Apeloig, *et al.*, unpublished results⁵⁰), which also have a planar radical center, are similar to those of radical **9**.

The cyclotetrasilanyl radical **15** (Figure 4) has an almost planar array of four silicon atoms, of which three (Si1, Si2, Si3) are trigonally coordinated.⁶⁷ The sum of bond angles around each of these silicon atoms (Si1–Si3) is 360.0°, 359.1°, and 356.2°, respectively. Si1 and Si2 have a planar geometry, but Si3 is slightly pyramidalized. The Si–Si bond lengths of 2.26 Å are intermediate between those of the Si=Si double bond (2.174 Å) and the Si–Si single bond (2.349–2.450 Å)⁷³ in the four-membered ring of

Figure 4 ORTEP diagram of the X-ray molecular structure of cyclotetrasilanyl radical **15**. [Adapted with permission from Ref. 67. Copyright 2001 American Chemical Society.]

hexakis-(*tert*-butyldimethylsilyl)cyclotetrasilene,^{67,74} supporting the occurrence of allylic delocalization of the unpaired electron.⁶⁷

2.3 EPR Parameters of Silyl Radicals

EPR spectroscopy is the most important spectroscopic tool for studying radicals (see **Analysis of Radicals by EPR**) and therefore a few general comments regarding the EPR parameters of silyl radicals are called for.

The EPR spectrum of silyl radicals consists of a central singlet signal characterized by its *g*-factor which results from the unpaired electron residing on the nonmagnetic ²⁸Si nuclei (95.33% natural abundance). This central signal is split by the central ²⁹Si nuclei (*I* = 1/2, 4.67% abundance) and by other magnetic elements present in the substituents. Substituents bonded directly to the silicon carrying the unpaired electron (α -position) affect significantly the EPR parameters of silyl radicals; the $a_{\text{Si}}(^{29}\text{Si}_\alpha)$ hyperfine coupling constants (*hfccs*) vary from 55.5 G for (*i*-Pr₃Si)₃Si⁴⁸ to 416 G for Cl₃Si⁷⁵ and to 498 G for F₃Si⁷⁶. These large

variations in $a(^{29}\text{Si}_\alpha)$ *hfccs* are attributed to changes in the geometry of the radical center, affecting its hybridization, and to the electronic effects of the α -substituents. Based on theoretical calculations, it was suggested that a higher electronegativity of the α -substituents and an increase in the degree of pyramidalization at the radical center lead to a larger contribution of the 3s orbital to the singly occupied molecular orbital (SOMO) and therefore to a larger $a_{\text{Si}}(^{29}\text{Si})$.^{51,57} Electronegative substituents (e.g., F, Cl) increase the degree of pyramidalization at the radical center and thus increase $a_{\text{Si}}(^{29}\text{Si})$,⁷⁶ while electropositive substituents (e.g., silyl groups, metals) lower the degree of pyramidalization, decreasing $a_{\text{Si}}(^{29}\text{Si})$.^{51,57} Bulky substituents reduce the degree of pyramidalization at the radical center, as the steric repulsion is minimal in a planar geometry, and therefore the larger the substituents the smaller the $a_{\text{Si}}(^{29}\text{Si}_\alpha)$ values. These effects are clearly evident in the EPR data presented in Tables 2 and 4.

Theoretical quantum mechanical calculations are very helpful in characterizing and studying silyl radicals. Thus, the calculated geometry and EPR spectrum are crucial for the correct assignment of a measured EPR spectrum to a specific radical and thus for its identification. In addition, the

calculations allow the evaluation of the role of the different effects that determine the magnetic properties of a given free radical. The importance of theory to radical research led in recent years to numerous computational studies using a variety of theoretical approaches and levels of sophistication.^{50,51,57–62, 69}

2.3.1 EPR Parameters of Tris(silyl)silyl Radicals

The EPR parameters, the degree of pyramidality, and the half-life of several persistent and stable tris(silyl) substituted silyl radicals are presented in Table 2. The g -factor values that are presented in the tables are given at the highest available measurement accuracy. The EPR parameters of a variety of alkyl, alkoxy, phenyl, halogen, and other short-lived α -substituted silyl radicals are summarized in Ref. 5 and are not repeated here.

The EPR spectra of tris(silyl) substituted silyl radicals are characterized by a central signal at g in the range of 2.0053–2.0065 which is split by hyperfine interactions. The $hfcc$ of the central silicon α - ^{29}Si , of 55–64 G, is much larger than the $hfcc$ with the β - ^{29}Si or the γ - ^{29}Si nuclei of the substituents (6–10 G). Additional splitting from the substituents' protons is generally very small (0.4 G) (Table 2). The g -factor is not sensitive to the substitution pattern.

A typical EPR spectrum of a stable silyl radical [$(t\text{-Bu}_2\text{MeSi})_3\text{Si}^\bullet$] (**9**) is shown in Figure 5. It consists of a central singlet signal at $g = 2.0056$ that results from the unpaired electron residing on

the nonmagnetic ^{28}Si nuclei, a doublet splitting with $hfcc$ of 58.0 G assigned to the coupling of the unpaired electron with the $^{29}\text{Si}_\alpha$ nucleus, and a doublet splitting having a higher intensity and a smaller $hfcc$ value (8.0 G) assigned to the $hfcc$ with three $^{29}\text{Si}_\beta$ nuclei (Figure 5a). Coupling with the methyl and t -butyl protons is also observed (the number of interacting nuclei is also given): $a_{\text{H}}(54^1\text{H}) = 0.14$ G; $a_{\text{H}}(9^1\text{H}) = 0.21$ G (Figure 5b).⁵⁰ An important observation is that $a_{\text{Si}}(^{29}\text{Si}_\alpha)$ is linearly dependent on the temperature in the range of 180–340 K, so that raising the temperature increases $a_{\text{Si}}(^{29}\text{Si}_\alpha)$ by 1.73 G/100 K (Y. Apeloig, *et al.*, unpublished results).⁶⁹ This temperature dependence is due to the out-of-plane vibrations of the substituents and is similar to that observed in planar alkyl radicals.⁷⁷ This temperature dependence must be taken into consideration when assigning EPR signals to new silyl radicals.

2.4 Reactions and Structure

2.4.1 Dimerization

The two major decay routes of silyl radicals are (i) dimerization to the corresponding disilane and (ii) hydrogen abstraction from the solvent or from the substituents of another silyl radical molecule. In the absence of scavengers, trapping reagents, or efficient H-donors, dimerization is the major decay route of silyl radicals and thus determines their lifetime. The rate of dimerization depends

Figure 5 (a) High-resolution EPR spectrum of $(t\text{-Bu}_2\text{MeSi})_3\text{Si}^\bullet$ in pentane; (b) Expanded central multiplet. [Adapted with permission from Ref. 50. Copyright 2009 American Chemical Society.]

Table 3 Kinetic data for dimerization of silyl radicals **1**, **5**, **6**, and **8**.

5	5×10^3	25	2.409
6	2×10^3	10	2.480
8	2×10^2	1	2.630

^aSecond order rate constant in $\text{M}^{-1} \text{s}^{-1}$.

on the dissociation energy of the central Si-Si bond (a thermodynamic factor) and on the size of the substituents and the steric effects which they exert (a kinetic factor). To demonstrate these effects, we discuss below the kinetic stability of several very reactive ($\tau_{1/2} \sim 0.1\text{--}1 \text{ s}$) $\text{R}_3\text{Si}^\bullet$ radicals (**1**, **5**, **6**, **8**, Table 3) toward dimerization to the corresponding oligosilanes $\text{R}_3\text{Si-SiR}_3$ (**1a**, **5a**, **6a**, and **8a**, respectively, Scheme 8).⁶⁵

The rate constants for the dimerization of radicals **5**, **6**, and **8** to produce the corresponding disilanes, shown as the backward reaction of (10), were

measured using EPR spectroscopy.⁶⁵ These radicals were generated photolytically ($\lambda \geq 300 \text{ nm}$), **5** from disilane **5a** (10) and radicals **6** and **8** from the corresponding silylmercury compounds (see Section 2.1.3). In the kinetic measurements, the light was turned off after a few seconds and the decrease in radical concentration $[C]$ as a function of time was measured by following the decrease in the intensity of the radical's EPR signal, as shown in Figure 6a for radical **6**. Good linear curves of $1/[C]$ versus time were obtained in all cases (e.g., Figure 6b). The resulting second-order reaction rate constants (k_{dim}) at 290 K are given in Table 3.⁶⁵

The dimerization rates in Table 3 cover a range of 500 000 and they are strongly dependent on the radical's substituents. The most reactive radical is **1** because the Me_3Si substituents are too small to effectively slow down its dimerization. The

**Scheme 8** Si-Si bond lengths ($\text{\AA}$) in **1a**, **5a**, **6a**, and **8a**.**Figure 6** EPR measurements of k_{dim} of radical **6**: (a) decay curve of the EPR signal at 290 K; (b) Plot of $1/[C]$ versus time. Figure 7 (a) Temperature dependence of the intensity of the EPR signal of radical **6**; (b) Plot of $\ln C^2$ versus $1/T$ for radical **6**. [Reproduced by permission from Ref. 65. Copyright 2005 Wiley-VCH Verlag GmbH & Co. KGaA.]

small steric repulsions in dimer **1a** are reflected in its relatively short Si–Si bond of 2.405 Å.⁵³ Substitution of the three Me₃Si substituents in **1** by three Me₃SiMe₂Si groups (**5**) has a significant effect on k_{dim} which is reduced by a factor of 20 000 relative to **1** (Table 3), but has only a minor effect on the central Si–Si distance which is 2.409 Å in **5a** (Scheme 8). When one of the Me₃Si groups in **1** is substituted by the bulkier *t*-Bu₂HSi substituent (i.e., **6**), the rate of dimerization decreases further and is slower by a factor of 5×10^4 relative to **1**. In this case, the central $r(\text{Si}–\text{Si})$ distance in its dimer **6a** is elongated considerably to 2.480 Å. Radical **8** with three *t*-BuMe₂Si substituents is the least reactive and its dimerization rate is by a factor of 25 slower than that of **5** and 5×10^5 times slower than that of **1**. In **8a** (which was not yet isolated) the calculated (ONIOM, MP2/6-31G(d):B3LYP/6-31G(d):HF/3-21G) central Si–Si distance is 2.630 Å,⁶⁵ significantly longer than that of **1a**. Density functional theory (DFT) calculations show that β -alkyl or β -silyl substitution have a negligible thermodynamic effect on the stability of silyl radicals^{47,55} and therefore the thermodynamic stabilities of **8** and **1** are expected to be nearly the same. The reason that **8** reacts 5×10^5 times more slowly than (Me₃Si)₃Si[•] is therefore kinetic in origin and is due to the effective steric protection of the radical center of **8** by the three *t*-BuMe₂Si substituents.⁶⁵ Similarly, radical **5** reacts 2×10^4 more slowly than **1**.⁶⁵ The effective protection of the radical center of **5** toward dimerization was explained by a protective substituents' "umbrella" around the radical center.⁶⁵ To obtain

silyl radicals stable at room temperature, the size of the substituents has to be increased beyond that in **8**, as is the case for **9** which is substituted with three large *t*-Bu₂MeSi substituents.

The enthalpies (ΔH) of the homolytic cleavage of the central Si–Si bond in disilanes can be obtained from temperature-dependent EPR measurements of the intensity of the radical's signal using (11), in which C is the concentration of the radical, T is the absolute temperature, and A is a constant. An example is shown in Figure 7 for radical **6**.⁶⁵ Temperature-dependent EPR measurements (Figure 7) yield ΔH values of 56 and 58 kcal mol^{−1} for the cleavage of the central Si–Si bond in **5a** and **6a**, respectively. These values are smaller by 9–11 kcal mol^{−1} than for Me₃Si–SiMe₃ (67 kcal mol^{−1}).⁷⁸ The weaker central Si–Si bond in **5a** and **6a** reflects the thermodynamic stabilization of the corresponding silyl radicals (**5** and **6**) by the α -silyl substituents relative to methyl groups (see also Table 1). The similar Si–Si bond cleavage energy in **5a** and **6a** reflects the fact that β -silyl substitution has practically no effect on the thermodynamic stability of the silyl radicals, in agreement with theoretical calculations,^{47,65} and the fact that the β -silyl groups in **5a** do not raise its ground state energy due to steric congestion as reflected in its short central Si–Si bond (Scheme 8).^{47,65} It was similarly estimated that ΔH for the cleavage of the central Si–Si bond of **8a** is only about 8 kcal mol^{−1}.⁶⁵ In agreement, at relatively high concentrations of **8a** ($\sim 10^{-2}$ – 10^{-3} M, hexane) obtained by oxidation of the corresponding anion, radical **8** was observed at 290 K due to the

8a $\rightleftharpoons$ **28** equilibrium.⁶⁵ The half-life of **8** at 298 K is ~ 1 day and it decays by hydrogen abstraction (Y. Apeloig, *et al.*, unpublished results).

$$\ln C^2 = \frac{\Delta H}{RT} - A \quad (11)$$

2.4.2 Photochemistry

Radical **9** is stable upon UV–Visible irradiation.⁵⁰ In contrast, the stable radical **12** (yellow solution in hexane) decays rapidly ($\tau_{1/2} \sim 100$ s) on irradiation at $\lambda > 400$ nm, to yield a 1:1 ratio of the corresponding disilene (blue colored) and the corresponding disilane (**12**).⁵⁰

The photoreactivity of **12** is due to its β -hydrogen. On irradiation, the radical undergoes photoexcitation (Scheme 9, step a), and then the photoexcited radical accepts an electron from another radical molecule forming an ion pair within a solvent cage (Scheme 9, step b) followed by proton transfer from the cation to the anion to yield the observed products (Scheme 9, step c).⁵⁰

Similarly, $(t\text{-Bu}_2\text{MeSi})_3\text{Si}^\bullet$ (**9**), which lacks β -hydrogens and is photostable, becomes photoreactive ($\tau_{1/2} \sim 100$ s), yielding $(t\text{-Bu}_2\text{MeSi})_3\text{SiH}$ in

the presence of hydrogen donors such as 2-propanol or triethylsilane.⁵⁰

2.4.3 Oxidation, Reduction, and Ionization

$(t\text{-Bu}_2\text{MeSi})_3\text{E}^\bullet$ ($\text{E} = \text{Si}, \text{Ge}, \text{Sn}$) radicals undergo both oxidation and reduction processes, yielding the corresponding cationic and anionic derivatives.⁶ Their first oxidation and reduction potentials in tetrahydrofuran (THF), as measured by cyclic voltammetry, are as follows: for the Si-centered radical $E_{\text{P(ox.)}} = 0.8$ V, $E_{1/2(\text{red.})} = -1.43$ V; for the Ge-centered radical $E_{\text{P(ox.)}} = 0.6$ V, $E_{1/2(\text{red.})} = -1.46$ V; and for the stable Sn-centered radical $E_{\text{P(ox.)}} = 0.2$ V, $E_{1/2(\text{red.})} = -1.41$ V.⁷⁹

UV photoelectron spectroscopy gives the following first ionization potentials for $(t\text{-Bu}_2\text{MeSi})_3\text{E}^\bullet$ ($\text{E} = \text{Si}, \text{Ge}, \text{Sn}$): 6.15 eV for $\text{E} = \text{Si}$; 6.0 eV for $\text{E} = \text{Ge}$; and 5.8 eV for $\text{E} = \text{Sn}$. These ionization energies correspond to the removal of an electron from the SOMO of the radicals and they decrease in the order $\text{Si} > \text{Ge} > \text{Sn}$, in agreement with the trend in their oxidation potentials and the ionization energies of the isolated atoms (Si (8.15 eV), Ge (7.90 eV), Sn (7.34 eV)).⁸⁰

Oxidation of radical **12** with HgF_2 yields the corresponding silyl fluoride (**12a**) (Scheme 10, path a), and its reduction with lithium metal in hexane or with $t\text{-Bu}_2\text{MeSiLi}$ in THF quantitatively yields the corresponding lithiosilane (**12b**) (Scheme 10, path b).⁵⁰ Oxidation of anion **12b** by GeCl_2 yields radical **12** (Scheme 10, path c).⁵⁰

2.5 Conformational Analysis of Stable Silyl Radicals in Solution

The preferred conformations of silyl radicals in solution can be determined by a combination of EPR spectroscopy and molecular orbital calculations. For demonstration, we discuss the conformations adopted in solution by oligosilyl radicals **12** and **13** (Table 2). Radical **12** was isolated and its structure was determined by X-ray crystallography. In the solid state, the radical center of **12** is planar ($\Sigma\theta = 359.8^\circ$)⁵⁰ similar to the stable radicals **9**⁴⁵ and **11** (Y. Apeloig, *et al.*, unpublished results). Calculation predict a planar Si center ($\Sigma\theta = 360^\circ$) also for radical **13**.⁵⁰

The EPR spectrum in hexane solution of **12** and **13**, both having a β -hydrogen, is shown in Figure 8. Both radicals exhibit the expected splittings with the α , β , and γ - ^{29}Si nuclei; that is, of 59.3, 7.3, and 10.4 G, respectively, for **12** (Figure 8a, Table 2), and 57.1, 7.5, and 10.0 G, respectively, for **13**. The g -factor and the $a_{\text{Si}}(^{29}\text{Si}_\alpha)$ and $a_{\text{Si}}(^{29}\text{Si}_\beta)$ values of **12** and **13** are typical for planar silyl radicals (Table 2). There is one important difference in the EPR spectra of the two radicals. The EPR spectrum of **13** exhibits a doublet arising from coupling with the β -hydrogen with $a_{\text{H}}(^1\text{H}_\beta) = 1.1$ G (Figure 8b),⁵⁰ which is missing

in the spectrum of **12**. This difference allows the determination of the conformation adopted by these radicals in hexane solution. Theoretically, the splitting constant by H_β depends on the angle θ between the $\text{H}_\beta\text{--Si}_\beta$ bond and the principal axis of the $\text{Si}(3\text{p})$ orbital occupied by the unpaired electron, according to (13), where B_0 and B are constants.⁸¹ $a(\text{H}_\beta)$ can, therefore, serve as a sensitive conformational probe.^{81–84}

$$a(\text{H}^\beta) = B_0 + B \cos^2 \theta \quad (13)$$

In **12** (Figure 8a), where a doublet splitting is not observed ($a(\text{H}_\beta) \leq 0.4$ G), θ is close to 90° . In contrast, in **13**, $a(\text{H}_\beta) = 1.1$ G (Figure 8b) and therefore $\theta \neq 90^\circ$. DFT calculations at the UB3LYP/TZVP//UB3LYP/6-31G(d) level support the above conclusion, yielding the conformations shown in Figure 9 where in **12** $\theta = 82^\circ$ and no spin density is found on H_β , while in **13**, $\theta = 63^\circ$ and some spin density resides on H_β . Solving (13), using the measured $a(\text{H}_\beta)$ for **13**, the absence of $a(\text{H}_\beta)$ for **12**, and the calculated θ angles, gives $B = 5.4$ G and $B_0 \sim 0$ G. Thus, in branched polysilyl radicals the maximum value of $a(\text{H}_\beta)$, when $\theta = 0^\circ$, is 5.4 G. Based on this value, it can be concluded for example that in radical **14** where $a(\text{H}_\beta)$ is 0.65 G, $\theta = 70^\circ$. (Y. Apeloig, *et al.*, unpublished results.)

3 BIS(SILYL) SILICON-CENTERED RADICALS $X(R_3Si)_2Si^\bullet$

The EPR parameters, degree of pyramidity, and the kinetic stability of both short-lived and stable bis(silyl)silyl radicals $X(R_3Si)_2Si^\bullet$ are collected in Table 4.

3.1 $H(R_3Si)_2Si^\bullet$

Hydrogen-substituted bis(silyl)-substituted silyl radicals $H(R_3Si)_2Si^\bullet$ (**16–20**) were generated by various reactions and were comprehensively studied by EPR spectroscopy and DFT calculations (Table 4).⁵¹ Two bulky silyl substituents at the Si-radical center, even large ones such as *t*-Bu₂MeSi, are not sufficient to prevent their fast dimerization, and the half-life of radicals **16–20** is of $\tau_{1/2} \sim 1$ s (Table 4). This is true also for the methyl-substituted radical **21**. The most reactive radical in the series, $H(Me_3Si)_2Si^\bullet$, was characterized only by its *hfcc* with $^1H_\alpha$ (11.0 G).⁸⁴ The calculated geometries of the $H(R_3Si)_2Si^\bullet$ radicals and their experimental *hfccs* show that they are slightly pyramidal; for example, in **16** $\Sigma\theta(Si) = 354.1$ (Table 4).

In contrast to silyl radicals **16–20** which have relatively short lifetimes, the homologous C-centered radicals with two bulky *t*-Bu₂MeSi substituents, that is, $H(t-Bu_2MeSi)_2C^\bullet$ (**28**) or alkyl radicals with one *t*-Bu₂MeSi group and one bulky alkyl substituent,

that is, $(t-Bu_2MeSi)(1-Ad)HC^\bullet$ (**29**), are persistent at 240 K.⁵¹ Evidently, these substituents are sufficiently large to prevent dimerization of the C-centered radical, but not of the silyl radicals. In agreement, radical **29** decays via a pseudo-first-order kinetics, which is consistent with an H-abstraction decay mechanism.⁵¹ Thus, the decay mechanism is different for Si-centered radicals and C-centered radicals carrying the same silyl substituents: that is, H-abstraction for C-centered radicals versus dimerization for Si-centered radicals. This difference in behavior is due to two main factors⁵¹: (i) Si–Si bonds are much longer than C–C bonds and steric effects of the substituents are therefore much more effective in determining the dimerization rate of C-centered radicals; (ii) The C–H bonds produced by H-abstraction are significantly stronger than Si–H bonds (e.g., 104.8 kcal mol^{−1} for H₃C–H vs 90.3 kcal mol^{−1} for H₃Si–H⁵²), thus favoring H-abstraction for C-centered radicals.

3.2 $R'(R_3Si)_2Si^\bullet$ ($R' = \text{phenyl, mesityl}$)

$R'(R_3Si)_2Si^\bullet$ where $R' = \text{phenyl}$ (**23**) or 2,4,6-trimethylphenyl (mesityl) (**24**) were synthesized according to (14) and their important properties are summarized in Table 4.^{50,69} Radical **23** is persistent at room temperature but could not be isolated, while radical **24**, carrying the more sterically congested mesityl group, can be isolated.

Figure 10 (a) EPR spectrum of radical **24** at 298 K; (b) Expanded central line at high resolution at 350 K.

The EPR spectrum of **24** (Figure 10a)⁶⁹ shows hyperfine coupling between the unpaired electron and both $^{29}\text{Si}_\alpha$ and $^{29}\text{Si}_\beta$. At high resolution, interactions with the hydrogens of the *tert*-butyl and methyl groups are also observed (Figure 10b).⁶⁹ The EPR spectrum of $\text{Ph}(t\text{-Bu}_2\text{MeSi})_2\text{Si}^\bullet$ (**23**) exhibits the same splittings, but with slightly different *hfccs* (Table 4). An interesting feature of both spectra is the absence of splitting from the aryl hydrogens. In contrast, such splitting were observed in the EPR spectra of the short-lived ($\tau_{1/2} \sim 1 \text{ s}$) trimesitylsilyl⁸⁵ and tris(3,5-di-*tert*-butylphenyl)silyl²³ radicals. The absence of *hfcc* with the aryl hydrogens in **23** and **24** shows that there is no delocalization of spin density into the π system of the aryl ring. Calculations for **23** and **24** (UB3LYP/6-31+G(d)) show that steric interactions force the aryl ring to be nearly perpendicular to the plane of the radical's SOMO, preventing conjugation with the aromatic π system.⁶⁹ For $\text{Ph}_3\text{Si}^\bullet$, calculations predict that the phenyl rings are rotated by $\sim 60^\circ$ relative to the SOMO's plane, resulting in small spin delocalization into the rings (Y. Apeloig, *et al.*, unpublished results).

3.3 Amino-Substituted Silyl Radical

$(t\text{-BuHN})(t\text{-BuMe}_2\text{Si})_2\text{Si}^\bullet$ (**25**) was generated by photolysis of $[(t\text{-BuMe}_2\text{Si})_2(t\text{-BuHN})\text{Si}]_2\text{Hg}$ (Y. Apeloig, *et al.*, unpublished results).⁶⁹ Radical **25** is significantly less stable than the analogous phenyl (**23**), mesityl (**24**), and adamantly (**27**) substituted

silyl radicals and its half lifetime is only 2–3 min. Calculations predict that **25** is pyramidal ($\Sigma\theta(\text{Si}) = 340.4^\circ$).⁶⁹ The EPR spectrum of **25** is characterized by $a_{\text{Si}}(^{29}\text{Si}_\alpha) = 91.7 \text{ G}$ and $a_{\text{N}}(^{14}\text{N}) = 2.2 \text{ G}$.

3.4 Triplet Silyl Biradical

The first stable triplet silyl biradical (**30**) was synthesized very recently by Sekiguchi and coworkers by the reductive dehalogenation of a *m*-bis(halosilyl)benzene (**15**) and was isolated and structurally characterized by X-ray crystallography.⁸⁶ The X-ray structure (Figure 11) shows that

Figure 11 ORTEP diagram of the X-ray molecular structure of biradical **30**. [Adapted with permission from Ref. 86. Copyright 2011 American Chemical Society.]

the half-filled 3p(Si) orbital and the aromatic ring orbitals are orthogonal to each other (similarly to **23** and **24**), an arrangement that does not allow C=Si π bonding. Both Si-radical centers have a nearly trigonal-planar structure ($\Sigma\theta(\text{Si}) = 358.6^\circ$). The EPR spectrum of **30** is typical for triplet species with $D' = 138.0 \text{ G}$ and $E' = 17.2 \text{ G}$. In contrast to *m*-bis(halosilyl)benzene, the isomeric *p*-bis(halosilyl)benzene when reacted with KC_8 yields a diamagnetic quinodimethane species featuring two exocyclic Si=C double bonds (16).⁸⁶

4 ANION RADICALS AND METAL-SUBSTITUTED SILYL RADICALS

One-electron reduction of low-coordinated organosilicon compounds (e.g., disilenes, disilynes, silylenes) by alkali metals yields the corresponding anion-radical salts. These species can exist as intimate ion pairs, solvent-separated ion pairs, or free ions with weak coulombic interaction with the cation, depending on the solvent. For simplicity, we use the term anion radicals for all these charged species in strongly solvating media (e.g., THF, dimethoxymethane (DME), crown-ethers). In contrast, in poor solvating media (e.g., hexane, toluene), a tight contact ion pair with significant Si–M bonding is formed and we classify it as a metal-substituted silyl radical.

4.1 Reduction of Multiply-Bonded Silicon-Compounds

4.1.1 Disilenes

Anion radicals of stable disilenes have been studied extensively and the ones that are persistent or stable are collected in Table 5. Weidenbruch *et al.* were the first to report the EPR spectra of disilene anion radicals, those of tetramesityldisilene

Table 5 EPR parameters and stability of persistent silyl anion radicals.

^a Atoms X responsible for the quoted $hfcc$ are given in parentheses.

(31) and of tetra-*tert*-butyldisilene (32) (Table 5), which were generated by the multiple reduction of the corresponding 1,2-dichlorodisilanes as the source of the disilenes and which were further reduced to the anion radicals.⁸⁷ Reduction of tetrakis(trialkylsilyl)disilenes: $R_2Si=SiR_2$, $R = SiPr-i_3$, $SiMe_2Bu-t$, $SiMePr-i_2$, by potassium in DME at room temperature gives the corresponding persistent disilene anion radicals **33–35**, respectively (Table 5).⁸⁸ Based on their *hfccs*, which are in the range 24–32 G (Table 5) and about one-half of the *hfccs* of the corresponding tris(trialkylsilyl)silyl radicals ($a(^{29}Si) = 55.5–63.8$ G) (Table 2), the authors concluded that the silicon atoms in **33–35** are nearly planar.⁸⁸

Reduction of $(t-Bu_2MeSi)_2Si=Si(SiMeBu-t_2)_2$ (**36a**) by *t*-BuLi in THF (17) yields the isolable anion radical **36** which crystallizes from THF as the $Li \cdot 4THF$ salt.⁸⁹

The molecular structure of **36** was determined by X-ray crystallography, which is shown in Figure 12.⁸⁹ The central Si1–Si2 bond length of 2.341 Å is 3.6% longer than that of disilene

36a (2.260 Å) and it is in the typical range of Si–Si single bonds. The twist angle around the central Si–Si bond, (i.e., the angles between the Si2–Si1–Si4 and Si5–Si2–Si6 planes) is 88°, indicating that, on reduction, the π (Si=Si) bond is broken, consistent with the extra electron entering the $\pi^*(Si=Si)$ orbital. The Si2 atom is planar ($\Sigma\theta(Si) = 359.9^\circ$), whereas Si1 is slightly pyramidal ($\Sigma\theta(Si) = 352.7^\circ$), indicating that Si2 has a radical character while Si1 has a silyl anion character.⁸⁹ The EPR spectrum of **36** (in 2-methyltetrahydrofuran at r.t.) shows a strong signal with $g = 2.0061$, accompanied by a pair of satellite lines (24.5 G) due to coupling of the unpaired electron with two magnetically equivalent silicon atoms,⁸⁹ indicating that the spin is delocalized over both the $^{29}Si1$ and $^{29}Si2$ nuclei.⁸⁹

4.1.2 Disilynes

Reaction of stable triply bonded disilyne **37a** with an equivalent amount of KC_8 in DME produces the disilyne anion radical **37**, which was isolated as dark brown crystals in 63% yield (18).⁹⁰ X-ray crystallography (Figure 13) reveals that **37** is a free anion radical with a Si1–K·4DME distance of 11 Å. The central Si–Si bond length of 2.1728(14) Å is 5% longer than in disilyne **37a** (2.0622(9) Å).⁹⁵ This is consistent with the notion that the additional

Figure 12 ORTEP diagram of the X-ray molecular structure of **36**. [Adapted with permission from Ref. 89. Copyright 2004 American Chemical Society.]

Figure 13 ORTEP diagram of the X-ray molecular structure of the disilyne anion radical **37**. [Adapted with permission from Ref. 90. Copyright 2007 American Chemical Society.]

electron enters the in-plane antibonding π^*_{in} orbital. The Si4–Si2–Si1 and Si3–Si1–Si2 angles of 112.8° and 113.9° respectively, are significantly smaller (i.e., the degree of bending is larger) than the corresponding bending angles of 137.4° in disilyne **37a**.⁹⁵ The fact that the two Si–Si–Si bending angles in **37** are essentially equal indicates that the unpaired electron is equally delocalized between the two central silicon atoms (Si1 and Si2).⁹⁰

The EPR spectrum of **37** shows a triplet signal with a g -value of 1.9996. The triplet splitting (2.3 G) arises from the interaction of the unpaired electron with the two protons of the isopropyl groups. The central signal is accompanied by two pairs of satellite signals, due to coupling with the two magnetically equivalent $^{29}\text{Si}1$ and $^{29}\text{Si}2$ nuclei ($a_{\text{Si}}(^{29}\text{Si}1) = a_{\text{Si}}(^{29}\text{Si}2) = 39.2$ G) and with two $^{29}\text{Si}_\beta$ nuclei, ($a_{\text{Si}}(^{29}\text{Si}_\beta) = 22.4$ G) (Table 5).⁹⁰

4.1.3 Phosphasilene

Reduction of phosphasilene $\text{R}_2\text{Si}=\text{PR}'$ (**38a**) with KC_8 yields the anion radical **38** (19), which is persistent at room temperature and was characterized by EPR spectroscopy.⁹¹ In THF, the EPR spectrum of **38** shows a doublet resulting from the coupling of the unpaired electron to the phosphorus nucleus ($a_{\text{P}}(^{31}\text{P}) = 54.0$ G), accompanied by a pair of silicon satellites ($a_{\text{Si}}(^{29}\text{Si}) = 50.0$ G). The EPR

spectrum changes dramatically when the solvent is changed to nonpolar benzene. $a_{\text{P}}(^{31}\text{P})$ decreases significantly to 15.0 G, whereas $a_{\text{Si}}(^{29}\text{Si})$ increases to 65.0 G. This change can be explained by the localized electronic structure of the anion radical in benzene (**39**), where both the unpaired electron and the negative charge are localized on Si_α , and a more delocalized structure in polar THF where the unpaired electron is localized on Si_α and the negative charge is mainly on P.⁹¹

4.2 Reduction of Silylenes

Several anion radicals of silylenes have been reported.^{92,93} Addition of crown-ethers in THF or DME to 1,2-dimetallasilane **40a** ($\text{M} = \text{Li}, \text{Na}$) leads to cleavage of the central Si–Si bond, yielding the corresponding stable silylene anion radicals ((20), Table 5).^{92,93} The EPR parameters of **40** are independent of the counter alkali cations (Li, Na), indicating that they are free ion pairs.

Scheme 11 Generation of Li- or Na-substituted silyl anion radicals **42** and **43**.

One-electron reduction of stable silylene (**41a**) by alkali metals yields the corresponding anion radicals **41** (21) (Table 5).⁹⁴ The EPR parameters of **41** in DME are $a_{\text{Si}}(^{29}\text{Si}_\alpha) = 29.9 \text{ G}$, $a_{\text{Si}}(^{29}\text{Si}_\gamma) = 13.0 \text{ G}$, and 16.6 G , $g = 2.0077$, and they are independent of the counter alkali cations (Li, Na, K, Cs, Rb), indicating that **41** is a free anion radical in DME.⁹⁴

Li- or Na-substituted silyl anion radicals **42** and **43** were observed when silylenoid **42a** was stirred at 330 K with lithium or sodium powder, respectively, in hexane (Scheme 11).⁹⁶ The EPR spectrum of **42** shows the expected quartet splitting of all signals by ^7Li ($I = 3/2$) and **43** shows quartet splitting of the signals by ^{23}Na ($I = 3/2$) (Table 5).⁹⁶

The $a_{\text{Si}}(^{29}\text{Si}_\alpha)$ values of anion radicals **40–43** (Tables 5 and 6) are the smallest and their g -values are the largest among related polysilyl radicals, indicating that the SOMO of **40–43** has a nearly pure $3p$ character.^{92–94, 96}

Comparison of the EPR spectra of **40**, **42**, and **43** in hexane and DME provides interesting information about their ionic character. In DME, $[(t\text{-Bu}_2\text{MeSi})_2\text{Si}]^{\cdot-} \text{Na}^+$ (**40**) has $a_{\text{Si}}(^{29}\text{Si}_\alpha) = 29.1 \text{ G}$, which is smaller than that of $(t\text{-Bu}_2\text{Me})_2\text{LiSi}^\cdot$ (**42**) or $(t\text{-Bu}_2\text{Me})_2\text{NaSi}^\cdot$ (**43**) in hexane, where $a_{\text{Si}}(^{29}\text{Si}_\alpha) = 33.0\text{--}34.0 \text{ G}$ (Table 6).^{96, 97} In **43**, $a_{\text{Na}}(^{23}\text{Na}) = 2.8 \text{ G}$, while in **40** coupling with ^{23}Na is not observed (Table 5).^{92, 93} This data is consistent with the description of these species as being covalently bound (i.e., metallosilyl radicals) in nonpolar solvents and separated anion radical ion-pairs in better solvating media such as ethers.

West *et al.* reported that the reduction of stable unsaturated N -heterocyclic silylene with potassium graphite in THF gives the corresponding 1,2-dilithiodisilane, which they suggested is formed via fast dimerization of the corresponding silylene anion-radical.⁹⁸

4.3 Alkali Metal- and Mercury-Substituted Silyl Radicals

Silyl radicals monosubstituted with Li (**42**) or Na (**43**) were discussed in Section 4.2.

4.3.1 Aggregated Silyllithium Radicals

Aggregated lithiosilanes are photolytic precursors to the interesting silyllithium aggregated silyl radicals **44** and biradical **45** (Scheme 12).⁹⁷ UV irradiation of a hexane solution of silyllithium dimer **44a** at 220 K yields a septet EPR signal (Figure 14a), which results from the splitting of the main line ($g = 2.007$) by two equivalent ^7Li nuclei ($I = 3/2$) with $a_{\text{Li}}(^7\text{Li})$ of 4.17 G . The hyperfine structure of the EPR signal and the cyclic structure of precursor **44a** allows the confident assignment of the observed signal to cyclic **44** (Scheme 12a), which is the first known silyl radical that is part of an aggregated silyllithium skeleton.⁹⁷ Addition of THF to a hexane solution of **44** yields the stable lithium-substituted silicon-centered radical **42** exhibiting a quartet EPR signal ($a_{\text{Si}}(^{29}\text{Si}_\alpha) = 33.25 \text{ G}$, $a_{\text{Si}}(^{29}\text{Si}_\beta) = 9.5 \text{ G}$, $a_{\text{Li}}(^7\text{Li}) = 1.5 \text{ G}$, $g = 2.007$) (Figure 14b, Table 6). Thus, the addition of THF to radical **44** cleaves its cyclic Si_2Li_2 skeleton (Scheme 12a).⁹⁷

UV irradiation of a frozen hexane solution (130 K) of silyl lithium aggregate **45a** (Scheme 12b) produces a characteristic EPR signal of a triplet biradical⁸¹ with four sidebands from $\Delta M_s = 1$

Table 6 EPR parameters of persistent alkali metal- and mercury-substituted silyl radicals.

transitions and a signal at half-field at 1675 G resulting from the forbidden $\Delta M_s = 2$ transition (Figure 14c).⁹⁷ The zero-field splitting parameter $|D'|$ of 172 G indicates a substantial interaction between the two radical centers with a calculated

distance (based on $|D'|^{81}$) of 435 pm, which is similar to that between the ring Si atoms in **45a** (457 pm).⁹⁷ This suggests that the two unpaired electrons are centered on the silicon atoms of the cyclic $\{(R'_2\text{Si})_2\text{Li}_2\}$ fragment with a geometry similar to

Figure 14 (a) EPR spectrum of **44** observed during UV irradiation of **44a** in hexane at 220 K. (b) EPR spectrum of silyl radical **42** observed after addition of THF to **44** in hexane at 300 K. (c) EPR spectrum of triplet bis(silyl) radical **45** (marked by “*”) during UV irradiation of **45a** at 130 K. The forbidden $\Delta M_s = 2$ absorption is shown in the inset. that in **45a** and thus the observed triplet bis-silyl radical is assigned the structure **45**.⁹⁷

4.3.2 Hg-Substituted Silyl Radicals

Photolysis ($\lambda > 300$ nm) for 10 s of silyl mercurials **46a** (22) and **47a** (23) or oxidation of **48a** (24) yields EPR spectra with g -factors of about 1.983 (Table 6).⁷¹ These g -factors are significantly smaller (upfield-shifted) relative to those of all other silyl radicals, which are in the range of $g = 2.004$ – 2.007 . The EPR spectra exhibiting the small g -factor (Figure 15) are assigned to mercury-substituted silyl radicals **46**–**48**. This assignment is supported by the observation of isotropic hyperfine interactions of the unpaired electron with the ^{199}Hg and ^{29}Si nuclei with satellite lines intensities corresponding to their natural abundances, and by the significantly upfield-shifted g -factor of 1.990 of the carbon analog $\text{ClHgH}_2\text{C}^\bullet$.⁹⁹

The magnitude of $a_{\text{Hg}}(^{199}\text{Hg})$ of 63–105 G in radicals **46**–**48** (Table 6) indicates that only 0.5–0.8% of the spin density resides in a 6s-type orbital of the mercury atom and the spin of these radicals is localized on the central silicon atom. This estimate is based on the fact that a full spin residing in the 6s orbital results in $a_{\text{Hg}}(^{199}\text{Hg})$ of $\sim 12\,000$ G.⁸¹ This huge $hfcc$ value implies that even small changes in the distribution of the spin density dictate meaningful changes in $a_{\text{Hg}}(^{199}\text{Hg})$.

Figure 15 EPR spectra of (a) radical **46** obtained after UV irradiation ($\lambda = 300$ nm) of a hexane solution of **46a** at 200 K; a line of a nonassigned hypersilyl radical is marked by an asterisk. (b) Radical **48** in hexane at 290 K. [Adapted with permission from Ref. 71. Copyright 2005 American Chemical Society.]

4.4 Transition-Metal-Substituted Silyl Radicals

The recent synthesis and isolation of stable silylenes¹⁰⁰ (and of other group-14 metallylenes^{101,102}) has opened new opportunities also for the synthesis of novel silyl radicals. New radicals, most of them persistent, were recently produced by Apeloig's group by the addition of transition-metal-centered radicals to stable *N*-heterocyclic silylenes,¹⁰³ germylene,¹⁰⁴ and carbene (Scheme 13).¹⁰⁵ These novel paramagnetic species **49–55** were studied by EPR spectroscopy (Table 7) and DFT calculations, revealing strong dependence of the spin density distribution on the nature of the main group E atom and of the transition metal M.

Two types of bonds form on addition of transition-metal fragments to divalent atoms: coordination (**A**) or covalent E–M (**B**) (Scheme 13). EPR spectroscopy combined with DFT calculations of

the produced metallo-silyl radical adducts allow the evaluation of the nature of the E–M bond in these paramagnetic species.

For example, the reaction of $(\text{CO})_5\text{Mn}^\bullet$ (produced by photolysis of $\text{Mn}_2(\text{CO})_{10}$) with unsaturated silylene **49a** yields radical **49** (25) which has a half-life of several weeks at room temperature. Radical **49** is characterized by a relatively small splitting of the main line by ^{55}Mn , ($a_{\text{Mn}}(^{55}\text{Mn}) = 8.9$ G) and by $a_{\text{N}}(2^{14}\text{N}) = a_{\text{H}}(2\text{H}) = 5.7$ G. The observed splitting by two magnetically equivalent ^{14}N nuclei and by two proton nuclei clearly indicates that the spin is delocalized over the entire heterocyclic moiety (type **B** in Scheme 13) (Table 7) (Y. Apeloig, *et al.*, unpublished results). Similarly, delocalized silyl radicals **51–53** of type **B** in Scheme 13 were observed in reactions of Re-, Co-, and Mo-centered radicals with silylene **49a**.^{103,104} In contrast, reaction of the analogous carbene with $(\text{CO})_5\text{Mn}^\bullet$ results in the substitution

Scheme 13 Formation of two bond types on the addition of transition-metal-centered radicals to the divalent center E of *N*-heterocyclic metallylenes.

Table 7 EPR parameters of persistent transition metal-substituted silyl radicals obtained by addition to silylenes.

of one of the CO ligands, yielding a persistent Mn-centered radical (**50**) ($a_{\text{Mn}}(^{55}\text{Mn}) = 24.0 \text{ G}$).¹⁰⁵ The large $a_{\text{Mn}}(^{55}\text{Mn})$ value and the lack of splitting by the nitrogen and proton nuclei indicate that this radical is of type A in Scheme 13, with the spin localized mainly on the manganese.¹⁰⁵ Similar

reactions of a variety of transition-metal-centered radicals with saturated silylene **54a** (26) do not lead to radical adducts, except with $(\text{CO})_5\text{Mn}^\bullet$ yielding a persistent Mn-centered radical (**54**) ($a_{\text{Mn}}(^{55}\text{Mn}) = 13.6 \text{ G}$, $g = 2.028$) (Y. Apeloig, *et al.*, unpublished results).

In contrast to transition-metal-substituted silyl radicals derived from heterocyclic silylene **49a**, which are usually persistent, radical adducts of silylenes **49a** (and **54a**) with phosphorus-centered radicals, such as $(i\text{-PrO})_2(\text{O})\text{P}^\bullet$, are highly reactive and they are not observed by EPR.¹⁰⁶

A persistent Re-substituted acyclic Si-centered radical **55** is produced by UV irradiation of a 1 : 1 mixture of silylenoid (**42a**)⁹⁶ and $\text{Re}_2(\text{CO})_{10}$ in toluene (27).⁵¹

The EPR spectrum of the irradiated mixture of reaction (27) reveals the presence of two rotamers of radical **55** (**55a** and **55b**) in the ratio of about 30 : 70 (Figure 16). The intensity ratio of the signals of the two rotamers does not depend on the irradiation time or the temperature (in the range of 230–320 K). According to DFT calculations, in the more stable rotamer, the *t*-butyl groups of the silyl substituents are in *anti* arrangement and in the less stable rotamer both *t*-butyl groups are in a *syn* arrangement, the *anti* rotamer being more stable by 0.6 kcal mol⁻¹.⁵¹

5 CONCLUSIONS AND OUTLOOK

The recent developments in the study of silyl radicals have been spectacular. Two decades ago, only short-lived silyl radicals were known and only few were spectroscopically characterized. Since then, many new types of persistent and stable silyl radicals have been synthesized, isolated, and characterized including by EPR spectroscopy and X-ray crystallography. These exciting developments were reviewed in this article.

Silyl radicals are of increasing interest not only to chemists but also to physicists and material scientists. We therefore believe that the chemistry of silyl radicals in general and of persistent and stable silyl radicals in particular will evolve in many new

directions in the future. Some of our thoughts on future developments are given below

1. Stable transition-metal complexes of silyl radicals may prove to be effective catalysts for a variety of reactions.
2. Stable silyl radicals may be used for photomagnetic switching.
3. The recently discovered photoreactivity of stable silyl radicals⁵⁰ may lead to the development of new, effective photoinitiators for radical polymerization.
4. Stable aggregates of metal-containing silyl radicals and silyl diradicals can be used as building blocks for novel molecular magnetic materials.
5. Synthesis of novel, stable silyl radicals and their isolation as crystalline materials may lead to novel molecular materials with unique properties. For example, our group has recently obtained a photoactive 1 : 1 cocrystal of $(t\text{-Bu}_2\text{MeSi})_3\text{Si}^\cdot$ with $(t\text{-Bu}_2\text{MeSi})_3\text{Si}^- \text{Li}^+ \cdot 4\text{THF}$ (Y. Apeloig, *et al.*, unpublished results.). This and similar cocrystals of silyl radicals and anions have the potential to exhibit interesting ionic and photoconductive properties.

ACKNOWLEDGMENTS

Our research on silyl radicals was supported by the Israel Science Foundation (ISF), by the USA–Israel Binational Science Foundation (BSF), and by the Minerva Foundation in Munich. BT is grateful to the Center for Absorption in Science, Israel, Ministry of Immigrant Absorption, State of Israel, for financial support. The authors are grateful to Dr Dmitry Bravo-Zhivotovskii for helpful discussions.

Physical Properties of Thiazyl Radicals Toward Conductive and Magnetic Materials

Kunio Awaga

*Research Center of Materials Science and Department of Chemistry, Nagoya University,
Chikusa-ku, Nagoya, Japan*

1 INTRODUCTION

Research on molecule-based conductors, superconductors, and magnetic materials has been characterized by the enhancement of dimensionality in intermolecular interactions. The first molecular metal, tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ), exhibited a Peierls transition due to instability of the one-dimensional (1D) conducting pathway formed by the π - π overlap.¹ Increasing the dimensionality to overcome the 1D instability led to the discovery of molecular superconductors, such as those based on the tetramethyltetraselenafulvalene (TMTSF) and bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF) donors.¹ More recent examples include the fullerene conductors, for example, K_xC_{60} , in which there are a three-dimensional (3D) network of C60 molecules.² A similar material development history is observed in the case of molecule-based magnetic materials. While the galvinoxyl radical, whose ferromagnetic interaction was found in the 1960s, exhibited a spin-Peierls-like transition, on which it lost its ferromagnetic properties,^{3–5} the first organic ferromagnet, p-NPNN, possessed a 3D network structure.^{6,7}

Heterocyclic thiazyl radicals possess unique chemical and physical properties.^{8–12} They can be

regarded as being on the borderline between organic and inorganic materials. They are chemically stable, in contrast to the instability of most organic radicals, so that they do not need protecting groups on their molecular skeletons. The lack of substituents permits relatively close packing in the solid state. Moreover, thiazyl radicals exhibit a large electronic polarization, leaving, respectively, a positively and a negatively polarized charge on sulfur and nitrogen. These charges form short intermolecular and interatomic S $\cdots$ N contacts. As a result, thiazyl radical solids often involve a multidimensional network consisting of face-to-face π - π overlaps and side-by-side S $\cdots$ N contacts. This is believed to bring about high- T_c magnetic ordering, conductive behavior, and hysteresis in phase transitions.

In this article, we describe the physical properties of thiazyl radicals, focusing on our recent studies on them. The studies on the other research groups are cited in the first figure of each section.

2 DRASTIC PHASE TRANSITIONS

Organic radicals often exhibit spin-Peierls-like phase transitions,¹³ associated with radical dimerization. Figure 1 shows the thiazyl radicals that are known to exhibit structural phase transitions.^{14–33}

Figure 1 Thiazyl radicals that exhibit a structural phase transition with a sudden change in the temperature dependence of magnetic susceptibilities: **1** (Refs 14, 15), **2** (Refs 14), **3** (Refs 16, 17), **4** (Refs 18, 19), **5** (Refs 20–24), **6** (Ref. 25), **7** (Ref. 25), **8** (Ref. 26), **9** (Ref. 27), **10** (Ref. 28), **11** (Ref. 29), **12** (Ref. 30), **13** (Ref. 31), **14** (Ref. 32), and **15** (Ref. 33).

They include very drastic transitions, probably reflecting the strong spin-lattice interactions of this radical family. The singly occupied molecular orbital (SOMO) of thiazyl radicals always have a nodal plane between bonded sulfur and nitrogen, so that an intermolecular short contact between the S–N chemical moieties does not automatically mean a large overlap between the SOMOs (Figure 2). It is expected that a small change in the intermolecular arrangement would bring a significant change in the intermolecular overlap, namely in the magnetic interaction.

Figure 2 An intermolecular overlap between SOMOs of neighboring thiazyl radicals. Owing to the presence of a node of the SOMO at the center of the S–N bond, the two orbitals have nearly an orthogonal relation. This suggests a possible ferromagnetic coupling and a drastic change in the overlap caused by a small change in the geometry. The latter is believed to bring about strong spin–lattice interactions in thiazyl radicals.

2.1 Room-Temperature Magnetic Bistability in TTTA

1,3,5-Trithia-2,4,6-triazapentalenyl (TTTA) (**5**, Figure 1) was first synthesized by Wolmershäuser and Johann in 1989.³⁴ Recently, it was found that TTTA exhibits a first-order phase transition with a surprisingly wide thermal hysteresis loop around room temperature.^{20–24} Figure 3a depicts

the temperature dependence of the paramagnetic susceptibilities χ_p for TTTA. The bold arrow in this figure indicates the value of χ_p for the virgin sample just after sublimation crystallization. As the sample is cooled from room temperature, χ_p shows a slight decrease. In this temperature range, the value of $\chi_p T$ is circa $0.2 \text{ emu K mol}^{-1}$, which is much smaller than that of the Curie spin. This is probably caused by a 3D antiferromagnetic

Figure 3 (a) Temperature dependence of the paramagnetic susceptibility χ_p for a polycrystalline sample of TTTA (5). The bold arrow indicates the χ_p value for the virgin sample just after sublimation. (b) Nearest neighbor intermolecular overlaps of TTTA in the HT and LT phases. The electrostatic interaction favors a shifted overlap, while the exchange interaction results in an eclipsed overlap. [Data taken from Ref. 20.]

interaction in the crystal of TTTA. At $T_{c\downarrow} = 230$ K, χ_p begins to decrease rapidly, becoming zero at 170 K; TTTA is intrinsically diamagnetic at low temperatures (LTs). When the sample is heated from a LT, a diamagnetic-to-paramagnetic transition is found at $T_{c\uparrow} = 305$ K, indicating the large hysteresis loop. Since this loop goes through room temperature (290 K), TTTA is regarded as a magnetically bistable material at room temperature.

Figure 4 shows the crystal structures of the high-temperature (HT) and the low-temperature (LT) phases of TTTA. The HT phase crystallizes in the monoclinic $P2_1/c$ space group. The structure consists of a polar 1D stacking column, in which the molecules are related by translational relations

with a constant interval. This stacking column is surrounded by six neighboring columns with very short $S \cdots N$ and $S \cdots S$ contacts. In contrast, TTTA exhibits a strong dimerization along the stacking direction in the crystal structure of the LT phase that belongs to the triclinic $P\bar{1}$ space group. This radical dimerization must be responsible for the diamagnetic properties of the LT phase. Figure 3b shows a schematic comparison between the nearest neighbor intermolecular arrangements in the two phases. It is notable that the molecules have an eclipsed overlap in the LT phase, in contrast to a shifted overlap in the HT phase. More specifically, the molecular planes in the LT phase dimer are not parallel; the distance between the $-S-N-S-$ moieties is shorter by circa $0.09 \text{ \AA}$ than that between the $-N-S-N-$ moieties, probably reflecting a bonding interaction between the unpaired electrons that are concentrated on the $-S-N-S-$ moieties. This suggests that bond formation is the main driving force of this phase transition.

It is expected that there is a competition between the exchange and electrostatic interactions (see Figure 3b). The exchange interaction favors an eclipsed overlap, such as that found in the LT phase, because this structure maximizes the intermolecular overlap between the SOMOs. However, this is the most disagreeable structure from the viewpoint of electrostatic energy because it includes intermolecular and interatomic contacts between polarized charges in the same sign, namely $S^{\delta+} \cdots S^{\delta+}$ and $N^{\delta-} \cdots N^{\delta-}$. It is presumably this competition that causes the drastic phase transitions in the thiazyl radical family.

Differential scanning calorimetry (DSC) measurements reveal an exothermic transition at 234 K on cooling and an endothermic one at 315 K on heating, respectively.²² The transition enthalpy ΔH values at $T_{c\downarrow}$ and $T_{c\uparrow}$ are determined to be 2210 and 2340 J mol^{-1} , respectively. The difference must be due to the fact that the HT and LT phases have different heat capacities. The transition entropies ΔS on cooling and heating are estimated to be $\Delta S_{\downarrow} = \Delta H_{\downarrow}/T_{c\downarrow} = 9.44 \text{ J K}^{-1} \text{ mol}^{-1}$ and $\Delta S_{\uparrow} = \Delta H_{\uparrow}/T_{c\uparrow} = 7.43 \text{ J K}^{-1} \text{ mol}^{-1}$, respectively. While the maximum estimation of the magnetic contribution is $R \ln 2$ ($= 5.76 \text{ J K}^{-1} \text{ mol}^{-1}$), the real contribution would be smaller than $R \ln 2$ because the HT phase involves rather strong antiferromagnetic interactions. Nevertheless, the ΔS values observed are larger than the maximum estimation. The excess

Figure 4 The crystal structures of TTTA (5): (a) the high-temperature phase and (b) the low-temperature phase. [Data taken from Ref. 20.]

Figure 5 Pressure dependence of the transition temperatures, $T_{c\uparrow}$ and $T_{c\downarrow}$, for TTTA (5). Solid curves are eye guides. [Data taken from Ref. 24.]

entropy indicates involvement of the lattice system in the phase transition.

The temperature dependence of χ_p of TTTA was studied under 0.38, 0.75, and 1.5 GPa, and the pressure dependences of $T_{c\uparrow}$ and $T_{c\downarrow}$ were obtained.²⁴ The results are shown in Figure 5, indicating that both $T_{c\uparrow}$ and $T_{c\downarrow}$ exhibit significant increases with an increase in pressure. Thus, the bistable range shifts toward higher temperatures. Although room temperature (290 K) is just below $T_{c\uparrow}$ at ambient pressure, it falls in the

center of the hysteresis loop at 0.75 GPa. That is, room-temperature bistability can be stabilized by pressure. The two solid curves in Figure 5 are only eye guides, but the gradients at the ambient pressure are estimated to be roughly $dT_{c\downarrow}/dp = 45 \pm 20 \text{ K GPa}^{-1}$ and $dT_{c\uparrow}/dp = 20 \pm 10 \text{ K GPa}^{-1}$. The theoretical value of dT_c/dp is given by the Clapeyron equation, $dp/dT_c = \Delta S/\Delta V = \Delta H/(T_c \Delta V)$, where ΔV is the volume change, though this equation is valid only under thermal equilibrium. The enthalpy changes for the transitions in TTTA are obtained by DSC measurements, as described above. The difference between the unit cell volumes of the two phases is $3.4 \text{ \AA}^3$ at room temperature.^{20,22} Since the unit cell contains four molecules, the volume difference is $\Delta V_{RT} = 3.4 N_A/4 \text{ \AA}^3 \text{ mol}^{-1}$, where N_A is Avogadro's constant. The theoretical value for dT_c/dp at $p = 0 \text{ GPa}$ can be estimated to be 60 K GPa^{-1} under the assumption that $\Delta V = \Delta V_{RT}$. The agreement between the theoretical and experimental values is fairly good (the same order of magnitude), and the equation can explain the shift toward higher transition temperatures with increasing pressure.

The phase control of TTTA was also achieved using photoirradiation.²³ There is a very clear chromism between the crystal surfaces of the two phases under a polarized microscope, namely between red-purple in the HT phase and yellow-green in the LT phase. The photoinduced transition from the diamagnetic LT phase to the

paramagnetic HT phase was observed after a single-shot (6-ns pulse) irradiation at 2.64 eV at 296 K. In addition, a clear threshold was identified in the dependence of the LT-to-HT conversion efficiency on the excitation photon density. This strongly indicated that the observation was not a thermal effect, but a photoinduced phase transition.

2.2 Spin-Gap Formation Versus Antiferromagnetic Ordering in BDTA

1,3,2-Benzodithiazolyl (BDTA) (**3**, Figure 1) was synthesized by Wolmershäuser *et al.* in 1984.³⁵ Awere *et al.*¹⁶ reported its crystal structure: it consists of a centrosymmetric dimer, where the dimer units form a two-dimensional network with short S...S contacts (Figure 6). This is very similar to the structure of the κ -modification of (BEDT-TTF)₂X (BEDT-TTF = bis(ethylenedithio) tetrathia-fulvalene, X = Cu(NCS)₂, etc.), known as *organic superconductors* whose critical temperatures exceed 10 K.³⁶ Awere *et al.*¹⁶ also reported that BDTA was diamagnetic at least below the room temperature because of strong antiferromagnetic interactions in the structure. In this section, we will describe the complex phase transitions in BDTA, where a diamagnetic spin-gap phase, a paramagnetic phase, an antiferromagnetic ordered phase, and a liquid phase, interplay.¹⁷

Figure 7 depicts the temperature dependence of χ_p for BDTA above room temperature (open circles). BDTA is diamagnetic at room temperature due to its dimerized structure.¹⁶ On heating, however, BDTA exhibits a first-order

Figure 6 The crystal structure of BDTA (**3**). [Data taken from Ref. 16.]

Figure 7 Temperature dependence of χ_p for BDTA (**3**) above room temperature. The gray plots indicate the effects of superheating and supercooling. [Data taken from Ref. 13.]

phase transition to a paramagnetic HT phase at 346 K, though the structure of this phase has not yet been identified. In the cooling process, a paramagnetic-to-diamagnetic transition is observed at 320 K, which is associated with the hysteresis of 26 K. This value is much smaller than that of TTTA, but still larger than the others in usual molecular solids. It is noted that this transition can be observed only for the aged BDTA samples, which probably include many lattice defects.

The most characteristic feature of BDTA is the occurrence of superheating and supercooling on phase transition above the room temperature. This always takes place in the case of fresh BDTA samples. The magnetic behavior in these nonequilibrium processes is shown in Figure 7 as gray circles. Figure 8 depicts the Gibbs free energy for BDTA determined by magnetic measurements and visual observation. In this figure, L and MO denote the liquid and antiferromagnetic ordered phases, respectively. The intersection between the LT and HT curves indicates the diamagnetic–paramagnetic phase transition at 346 K. On further heating of the superheated LT phase, the material melts at 360 K once, but the liquid immediately solidifies into the HT phase even on heating. This is because the free energies decrease in the order $LT > L > HT$ in the 360–364 K range. On heating, the LT phase relaxes into the HT phase through the L phase at 360 K. At 364 K, solid BDTA in the

Figure 8 Gibbs energy phase diagram for BDTA (3). HT, high-temperature phase; LT, low-temperature phase; L, liquid; MO, antiferromagnetic ordered state. [Data taken from Ref. 13.]

HT phase exhibits a second melting. This process has been called *double melting* and has been observed, for example, in molecular crystals and organic polymers.³⁷

Supercooling of the HT phase also occurs (Figure 7) and further cooling results in antiferromagnetic ordering at 11 K (Figure 8). The temperature dependence of χ_p for the supercooled HT phase follows the Curie–Weiss law with $\theta = -93$ K and $C = 0.375$ emu K mol⁻¹ (fixed), where θ and C are the Weiss and Curie constants, respectively. Below 15 K, χ_p shows a slight decrease with a rather abrupt change around 11 K, suggesting the antiferromagnetic ordering. The temperature dependence of the heat capacity c_p exhibits a λ -shaped anomaly at 11 K, supporting the antiferromagnetic ordering at this temperature. The HT phase transforms into the MO phase below 11 K, as indicated in Figure 8. The structures of the HT and MO phases must be nearly the same. Thus, it is thought that the crystal structures for the spin-gap state and the antiferromagnetic ordered state are switched at the phase transition at 346 K. Alternative relationships between the spin gap state and the antiferromagnetic ordered state have been reported in low-dimensional magnetic materials, such as spin-Peierls compounds³⁸ and copper-oxide high- T_c superconductors.³⁹ While the competition between the two states occurs on the identical crystal structure in these materials, BDTA forms two states with different crystal structures that are linked at the structural phase transition.

2.3 Charge Transfer Phase Transition in (BDTA)₂[Co(mnt)₂]

A donor–acceptor-type organic charge-transfer (CT) complex, TTF-chloranil, exhibits a neutral-ionic phase transition, at which the degree of CT changes from 0.3 to 0.7 with various critical phenomena including quantum behavior.^{40,41} Recently, CT phase transitions have been observed in several transition-metal complexes.^{42–44} In this section, we will describe a CT phase transition in (BDTA)₂[Co(mnt)₂] (mnt²⁻ = maleonitriledithiolate) (12), which is accompanied by characteristic changes in molecular structure, intermolecular packing, and magnetic susceptibility.

Figure 9 shows the values of $\chi_p T$ for (BDTA)₂[Co(mnt)₂] against temperature T .³⁰ In the temperature range 200–300 K, the $\chi_p T$ value (0.61 emu K mol⁻¹) depends little on temperature, obeying the Curie law. On cooling, however, $\chi_p T$ rapidly decreases to 0.49 emu K mol⁻¹ at 180 K, followed by a Curie–Weiss behavior with a Weiss constant of $\theta = -4.7$ K. Figure 9 also shows the $\chi_p T$ values on heating, revealing a hysteresis loop of 20 K at the transition. This indicates that the anomaly at 190 K is caused by a first-order phase transition.

The geometry of (BDTA)₂[Co(mnt)₂] at 253 K is shown (Figure 10, b), in which one half of the unit is crystallographically independent.³⁰ The molecular planes of BDTA and [Co(mnt)₂] are nearly parallel, and the axial positions of the cobalt ion are occupied by the sulfurs on separate BDTA molecules at a distance of 3.1672(9) Å. This value is nearly the same as the interplanar distance, suggesting that BDTA should be regarded as a counter cation for [Co(mnt)₂]. It is known that the S–N bond length l_{SN} of BDTA is a good indicator of the charge ρ_{BDTA} on it. The removal of the unpaired electron in the SOMO of BDTA shortens the S–N bond lengths because the SOMO has an antibonding character on the S–N bonds. There is an empirical linear relation between l_{SN} and ρ_{BDTA} , with which ρ_{BDTA} is estimated to be 0.9 for BDTA in the HT phase; this corresponds to the formula (BDTA^{0.9+})₂[Co(mnt)₂]^{1.8-}. Since BDTA⁺ and [Co(mnt)₂]²⁻ are $S = 0$ and $1/2$ spin species, this formula unit possesses one unpaired electron.

Figure 9 Temperature dependence of $\chi_p T$ for $(\text{BDTA})_2[\text{Co}(\text{mnt})_2]$ (**12**). The inset shows a possible mechanism of coordination bond formation at the phase transition of 190 K. [Data taken from Ref. 30.]

Figure 10 Crystal structures of $(\text{BDTA})_2[\text{Co}(\text{mnt})_2]$ (**12**) at 100 K (a) and 253 K (b). [Data taken from Ref. 30.]

The asymmetric unit of $(\text{BDTA})_2[\text{Co}(\text{mnt})_2]$ at 100 K includes two crystallographically independent BDTA molecules, A and B (Figure 10, a).³⁰ There is a Co...S axial coordination bond of 2.6163(18) Å between BDTA^{A} and $[\text{Co}(\text{mnt})_2]$,

while the Co...S distance is 3.5152(16) Å on the B side. Moreover, BDTA^{A} is significantly different in molecular structure; the average S–N bond length l_{SN} for BDTA^{A} (1.623(3) Å) is much longer than those for BDTA^{B} (1.605(3) Å) and BDTA in the

HT phase (1.603(2) Å). The charges on the two BDTA molecules in the LT phase are estimated to be $\rho_{\text{BDTA}}^{\text{A}} \approx 0.5$ and $\rho_{\text{BDTA}}^{\text{B}} \approx 0.9$, respectively. These values suggest a partial CT at the phase transition, namely $(\text{BDTA}^{0.9+})_2[\text{Co}(\text{mnt})_2]^{1.8-}$ (253 K) $\rightarrow$ $(\text{BDTA}^{0.9+})(\text{BDTA}^{0.5+})[\text{Co}(\text{mnt})_2]^{1.4-}$ (100 K).

The structural analyses indicate a partial CT by circa 0.4 for the phase transition at 190 K. This is further supported by the g -factors for the two phases, which are estimated from the Curie constants obtained by magnetic measurements to be $g = 2.55 \pm 0.10$ and 2.29 ± 0.10 for the HT and LT phases, respectively. Since the g -factor is governed by the distribution of the unpaired electron in the $(\text{BDTA})_2[\text{Co}(\text{mnt})_2]$ unit, it can be written as follows:

$$g^2 = (2 - 2\bar{\rho}_{\text{BDTA}})g_{\text{BDTA}}^2 + (2\bar{\rho}_{\text{BDTA}} - 1)g_{[\text{Co}(\text{mnt})_2]}^2 \quad (1)$$

where $\bar{\rho}_{\text{BDTA}}$ is the average charge on BDTA and g_{BDTA} ($= 2.006$) and $g_{[\text{Co}(\text{mnt})_2]}$ ($= 2.526$ of $[\text{N}(\text{C}_4\text{H}_9)_4]_2[\text{Co}(\text{mnt})_2]$) (Y. Umezono, W. Fujita, K. Awaga, H. B. Cui, and H. Kobayashi, unpublished data) are the g -factors for the neutral $S = 1/2$ BDTA radical and the $S = 1/2[\text{Co}(\text{mnt})_2]^{2-}$ dianion, respectively. Using the values of $\bar{\rho}_{\text{BDTA}}$ indicated in the structural analyses, 0.9 and 0.7 for the HT and LT phases, the two g -factors are calculated to be 2.43 and 2.23, respectively. These values are roughly in agreement with the corresponding values estimated from the Curie constants; the magnetic jump at the phase transition can be explained by the partial CT between BDTA and $[\text{Co}(\text{mnt})_2]$.

The structural and magnetic analyses reveal the CT phase transition, $(\text{BDTA}^{0.9+})_2[\text{Co}(\text{mnt})_2]^{1.8-}$ (253 K) $\leftrightarrow$ $(\text{BDTA}^{0.9+})(\text{BDTA}^{0.5+})[\text{Co}(\text{mnt})_2]^{1.4-}$ (100 K). This change in the degree of CT is smaller than those for the other CT transitions in the transition-metal complexes^{40,41}; that such a small change should bring about the coordination bond formation is peculiar to the present transition. This can be qualitatively explained (the inset of Figure 9). The electron transfer from $[\text{Co}(\text{mnt})_2]^{2-}$ to BDTA^+ through the π overlap decreases the positive charge on BDTA^+ and enhances the ability of BDTA to act as a ligand. Thus, BDTA forms a coordination bond, giving back the obtained electron partially to the vacant d-orbitals of the

cobalt ion in $[\text{Co}(\text{mnt})_2]$. This back donation makes the degree of CT smaller as a result. The phase transition in $(\text{BDTA})_2[\text{Co}(\text{mnt})_2]$ is considered to reflect a competing duality of BDTA as cation and ligand.

3 FERROMAGNETIC COUPLING AND ORDERING IN THIAZYL RADICALS

Figure 11 shows the thiazyl radicals that exhibit ferromagnetic intermolecular interactions and/or ferromagnetic (ferrimagnetic) ordering.^{45–55} The most well-known example is radical **17**, prepared by Banister *et al.*⁴⁶ This compound exhibits weak ferromagnetism with $T_N = 36$ K under high pressure (1 GPa).

3.1 Coordination Polymer in TTTA-Cu(hfac)₂

Thiazyl radicals are useful as ligands of transition-metal complexes.⁵⁶ The crystal structure of a 1:1 molecular compound, TTTA-Cu(hfac)₂ (**22**, Figure 11, Cu(hfac)₂ = bis(hexafluoroacetylacetonato)-copper(II)), is shown in Figure 9.⁵⁰ TTTA molecules occupy the axial positions of the elongated octahedron around the Cu(II) ion, and bridge the distance between the Cu(II) ions, resulting in an infinite zigzag chain along the b -axis. While various nitronyl nitroxides⁵⁷ and polynitroxyl radicals⁵⁸ are known to act as a bidentate bridging ligand and to form polymeric coordination compounds, the structure of TTTA-Cu(hfac)₂ clearly indicates similar chemical capability of the polycyclic thiazyl radicals. As shown in Figure 12, the Cu(II) ion is sandwiched between two TTTA molecules, labeled A and B, at distances of 2.342 and 2.478 Å from the Cu(II) ion. The former distance is shorter by more than 0.1 Å. The molecular plane of TTTA^A is nearly orthogonal to the plane defined by the four hfac oxygen atoms, while that of TTTA^B is significantly tilted.

The magnetic couplings between Cu(hfac)₂ and nitroxyl radicals have been previously discussed by Caneschi *et al.*⁵⁷ They explained the ferromagnetic couplings in these materials in terms of the orthogonality between the $d_{x^2-y^2}$ orbital of Cu(II) and the SOMOs of the organic radicals. By analogy, it is expected that the interaction between

Figure 11 Thiazyl radicals that exhibit a ferromagnetic coupling and/or a magnetic ordering: **16** (Ref. 45), **17** (Ref. 46), **18** (Ref. 47), **19** (Ref. 48), **20** (Ref. 48), **21** (Ref. 49), **22** (Ref. 50), and **23** (Refs 51–55).

Figure 12 Crystal structure of coordination polymer, TTTA-Cu(hfac)₂ (**22**). [Data taken from Ref. 13.]

Cu(hfac)₂ and TTTA^A would be ferromagnetic. However, the Cu(hfac)₂–TTTA^B interaction is probably antiferromagnetic due to the overlap between the magnetic orbitals of Cu(II) and TTTA^B caused by the tilted structure.

The $\chi_p T$ value for TTTA-Cu(hfac)₂ increases with decreasing temperature down to circa 30 K, indicating a ferromagnetic coupling. After passing through a maximum at this temperature, $\chi_p T$ shows an abrupt decrease, suggesting a weak antiferromagnetic coupling between the ferromagnetic units. This is quite consistent with the coordination around the Cu(II) ion. The ferromagnetic coupling constant was determined to be $J/k_B = 5.1$ K. This is stronger than those in the axial coordination compounds

of Cu(hfac)₂ and nitroxyl radicals,⁵⁷ presumably because the energy level of the SOMO of TTTA is closer to those of the d-orbitals of Cu(II).

3.2 Ferromagnetism in BBDTA Salts Driven by Evaporation of Crystal Solvent

BBDTA was initially reported independently by Wolmershäuser *et al.*⁵¹ and by Wudl and coworkers.^{59,60} Wolmershäuser *et al.*⁵¹ also reported the crystal structure and the ⁵⁷Fe Mössbauer spectra of the radical cation salt BBDTA·Fe(III)Cl₄·CH₃CN (**23**, Figure 11), which suggested antiferromagnetic ordering of the Fe³⁺ magnetic moments below 6.6 K.

Figure 13 Temperature dependence of $\chi_p T$ for BBDTA·GaCl₄ (**23**) in the solvated (●) and nonsolvated form (○). The inset shows the temperature dependence of χ_{ac} for the nonsolvated form. [Data taken from Ref. 52.]

BBDTA·GaCl₄·CH₃CN is isostructural to BBDTA·FeCl₄·CH₃CN, consisting of a face-to-face radical dimer. The crystal solvent, CH₃CN, occupies the space beside BBDTA, coordinating to the sulfur atom. These dimers are stacked via short S···N contacts, forming a ladder-type structure. The GaCl₄[−] anions are located between the ladder layers. As shown in Figure 13 as closed circles, the $\chi_p T$ values for BBDTA·GaCl₄·CH₃CN are nearly zero in the whole temperature range. This nonmagnetic property can be ascribed to a strong antiferromagnetic interaction in the dimer.

There is a dramatic change in the bulk magnetic properties after evaporation of the crystal solvent. The open circles in Figure 13 show the magnetic data for a sample in which 75% of the CH₃CN has been removed by evacuation for 96 h. This material exhibits paramagnetism, in remarkable contrast to the nonmagnetic properties of the solvated form. The values of $\chi_p T$ show a gradual increase, suggesting a ferromagnetic coupling. Below 10 K, $\chi_p T$ increases rapidly, reaching 1.82 emu mol^{−1} at 6 K. The inset in Figure 13 shows the temperature dependence of the ac susceptibilities (χ' : in-plane, χ'' : out-of-plane) for the same sample. The plots of χ' show an anomaly below 6.7 K with a rapid increase in χ , indicating ferromagnetic ordering. The isothermal magnetization curve at 2 K for this sample shows an abrupt increase at lower fields

followed by quick saturation above 400 Oe. The presence of a negligibly small hysteresis loop with a width of less than 10 Oe indicates that the material obtained is a soft magnet.

The crystal growth of the solvent-free BBDTA·GaCl₄ revealed the polymorphism of this material; there were at least three forms, α (plates), β (needles), and γ (blocks). The γ -phase exhibits a ferromagnetic transition at 7.0 K in contrast to the diamagnetic properties of the other two forms, suggesting that the desolvated material obtained from BBDTA·GaCl₄·CH₃CN would be in the γ -phase.⁵⁴

BBDTA·FeCl₄·CH₃COCH₃ is isostructural to BBDTA·GaCl₄·CH₃CN and exhibits similar solvation effects. While the solvated material exhibits paramagnetic behavior with antiferromagnetic ordering at 6.3 K, the desolvated material includes a ferrimagnetic phase with $T_N = 44$ K.⁵³ This is much higher than the transition temperatures of the parent materials: 7 K for the ferromagnetic transition in BBDTA·GaCl₄ and 3 K for the antiferromagnetic transition in (C₂H₅)₄N·FeCl₄.⁶¹ A strong antiferromagnetic coupling between the magnetic moments on BBDTA and FeCl₄ is thought to afford this organic/inorganic hybrid system a higher ferrimagnetic transition temperature.

4 CONDUCTIVE THIAZYL RADICALS

Figure 14 shows the conductive thiazyl radicals with a room-temperature conductivity above 10^{−2} S cm^{−1}.^{62–69} Most of these materials were synthesized by the group of Oakley. The compounds in Figure 14 are all ion radical salts of thiazyl radicals, and exhibit semiconductive behavior, except the HT phase in **24**.

4.1 Carrier Doping for Mott Phase in TTTA

The magnetic bistability of TTTA (**5**) has been described in Section 2.1. Although the HT phase of this material consists of nearly regular stacking columns with electrostatic intercolumn interactions, this phase exhibits very poor conductivity of 10^{−8} Ω^{−1} cm^{−1} at room temperature with an activation energy of 0.33 eV under vacuum.¹² The conductivity for the LT phase is two orders of

Figure 14 Conductive thiazyl radicals with a room-temperature conductivity higher than $10^{-2} \text{ S cm}^{-1}$: **24** (Ref. 62), **25** (Ref. 63), **26** (Ref. 64), **27** (Ref. 65), **28** (Refs 66, 67), **29** (Refs 68, 69), and **30** (Refs 68, 69).

Figure 15 Time dependence of the conductivity of TTTA (**5**) during I_2 doping. [Data taken from Ref. 13.]

magnitude lower. Thus, it is highly possible that the HT phase can be regarded as a Mott insulator: strong on-site electron–electron repulsion results in electron localization.

Figure 15 shows the effects of I_2 doping for the HT phase of TTTA. The conductivity σ is quickly enhanced by four or five orders of magnitude, followed by saturation after 10 h.¹² This saturation is presumably due to a breakup of the crystal structure caused by penetration of the dopant. It is clearly

demonstrated that hole doping of the HT phase of TTTA brings about significant enhancement of the conductivity.

4.2 Nonlinear Electrical Transport in $\text{NT}_3 \cdot \text{GaCl}_4$

Barclay *et al.*⁶⁴ prepared NT and its 3:2 radical cation salt, $\text{NT}_3 \cdot (\text{BF}_4)_2$ (**27**). The crystal of **27**, consisting of $(\text{NT})_2^{2+}$ and NT^0 , exhibited relatively high conductivity.⁶⁵ Figure 16 schematically shows the network structure in the crystal of the 3:1 salt of NT, $\text{NT}_3 \cdot \text{GaCl}_4$ (**28**).^{66,67} This crystal consists of four kinds of NT molecules, denoted **a**, **b**, **c**, and **d**, with significantly different molecular structures. The molecules **a** and **b** form a two-dimensional (2D) square network with short, electrostatic $\text{S}^{\delta+} \dots \text{N}^{\delta-}$ contacts (layer A), and the molecules **c** and **d** form a similar network (layer B). The two layers are stacked with large π – π overlaps in the manner of BABBAB. The counter anion GaCl_4^- is located in a cavity surrounded by the four stacking columns of NT.^{66,67}

From the S–N bond distances, the charges on the four NT molecules are estimated to be 0.8 (molecule **a**), 0.5 (**c**), 0.1 (**b**), and 0 (**d**), respectively. The molecules **a** and **c** are charge-rich (R) and charge-intermediate (I), respectively, while molecules **b** and **d** are charge-poor (P). This clearly

Figure 16 Schematic view of the crystal structure on (NT)₃[GaCl₄] (**28**). The molecules **a–d** are crystallographically independent. (a) 2D network structure caused by short S···N contacts. (b) Side view of the layered structure. [Data taken from Ref. 66.]

Figure 17 J – E characteristics for a crystal of (NT)₃[GaCl₄] (**28**) at various temperatures, taken by pulse field (25-ms width and 300-ms interval). The open circles show the turning points for the negative resistance effect. [Data taken from Ref. 66.]

indicates a 3D charge ordering. It is notable that the charge-rich (or -intermediate) and -poor molecules occupy the warp and weft positions in the 2D square network, in which the combination of R–R, I–I, or P–P is ruled out. Such a 3D charge alternation is gaining much attention as a characteristic insulating

state induced by intermolecular Coulomb repulsions in strongly correlated systems.^{70,71}

NT₃·GaCl₄ exhibits semiconductive properties with $\sigma_{\text{RT}} = 0.5 \text{ S cm}^{-1}$ and $\Delta E = 0.18 \text{ eV}$, where σ_{RT} is the room temperature conductivity and ΔE is the activation energy. Figure 17 shows the temperature dependence of the current density (J)–electric field (E) characteristics for NT₃·GaCl₄.^{66,67} At room temperature (290 K), the J – E curve exhibits a steep nonlinear rise and clearly indicates a so-called negative differential-resistance effect after passing through the turning point indicated by an open circle in this figure. This nonlinearity is considered to be caused by a partial melting of the charge ordering, because, if there is no charge ordering, the present material should have a five-sixth filled band that brings about metallic conduction. The threshold values for the electric field E_{T} and the current density J_{T} are 100 V cm^{-1} and 60 A cm^{-2} , respectively. It is very rare that this type of negative resistance effect is observed at room temperature in organic materials. In addition, the E_{T} value obtained for NT₃·GaCl₄ is much lower than those of the other organic materials showing nonlinear conductivity.^{8,72–78} By lowering the temperature from 290 K, the values of E_{T} and J_{T} exhibit a significant increase and decrease, respectively, making the negative resistance effect more drastic.

Figure 18 shows the effects of the DC current on the electron paramagnetic resonance (EPR) spectra of NT₃·GaCl₄ appearing at $g = 2.005$.⁶⁷ This value is typical for thiazyl radicals. When the current is loaded, the signal intensity exhibits a quick decrease and becomes one-third of the

Figure 18 Current effects on the X-band EPR of $\text{NT}_3\text{-GaCl}_4$ (28). [Data taken from Ref. 67.]

original value at $J = 160 \text{ A cm}^{-2}$. In general, the current-induced nonlinear transport is inevitably associated with generation of the Joule heat, while most of them are probably diffused through the electrical wires. If the observed EPR behavior is only caused by heating, we need to assume an unrealistic sample temperature of $\sim 900 \text{ K}$. If the crystals of $\text{NT}_3\text{-GaCl}_4$ become homogeneously more conductive with an increase in J , there should be a line width broadening, caused by delocalization of the unpaired electrons. However, this is not the case. In general, the high conductive states induced by J are believed to be caused by the formation of filaments: the highly conductive pathways formed in the samples inhomogeneously.^{77,79,80} By analogy, the observed J dependence of the EPR for $\text{NT}_3\text{-GaCl}_4$ can be attributed to the inhomogeneous formation of highly conductive pathways, such as filament and surface, which shield the remaining part of the crystal from EPR microwave.

4.3 Photoconductivity of BDTDA

BDTDA is a so-called disjoint diradical, so that the molecular orbitals for the two unpaired electrons would be localized to separate five-membered rings and the exchange interactions between the two radical centers would be very small.⁶² The crystal structure of BDTDA consists of a face-to-face dimer, reflecting that the intermolecular interaction is stronger than the intramolecular interaction. Although BDTDA-I (24) is conductive,⁶² BDTDA

Figure 19 Photocurrent of an ITO/BDTDA/Al sandwich cell exposed to the 532-nm laser under 1.59-mW cm^{-2} irradiation from the ITO side at a reverse bias of -3 V (a) and at zero bias condition (b). [Data taken from Refs 81 and 86.]

itself is a poor conductor probably due to this dimerization. However, BDTDA can form highly oriented thin films that are expected to include a wide conduction band consisting of the LUMOs of the radical dimers.⁸¹ Figure 19a shows the photocurrent of an (+)ITO|BDTDA(300 nm)|Al(−) photocell, induced by the illumination of a green laser (532 nm) with a small reverse bias voltage V_{bias} of -3 V .⁸¹ BDTDA thin films exhibit a very high conductivity with a photoresponsivity of 3.5 mA/W and an on/off ratio of approximately 10^3 . They are comparable to those of the most-advanced organic polymer photodetectors for visible region.^{82–85}

Figure 19b shows the no-bias photocurrent of the same BDTDA photocell.⁸⁶ On illumination, a very large transient current appears, followed by a steady-state photocurrent and a negative spike just after the illumination. The quantum efficiency for the positive peak photocurrent reaches as high as 65% at the photon energy of 2.8 eV . This anomalous transient photocurrent is interpreted in terms of a highly efficient displacement current⁸⁷ caused by the establishment of a photoinduced space-charge zone and the bulk polarizations in the BDTDA films. The photoinduced displacement current in organic radical solids can provide a new operational principle for optoelectric conversion.

5 CONCLUSION

Thiazyl radicals are promising materials to exhibit unusual physical properties, such as drastic phase transitions, ferromagnetic couplings, and high conductivities, reflecting their chemical stabilities, strong intermolecular interactions, multidimensional crystal structures, and strong spin–lattice interactions. More interestingly, these properties can be manifested and/or modified by making intermolecular compounds; thiazyl radicals are useful building blocks of supramolecular compounds, because they can act as counter cations, donors, and ligands. In the near future, thiazyl radicals are expected to be utilized in developing organic electronics/spintronics.

Department of Chemistry, Centre for Catalysis Research and Innovation, University of Ottawa, Ottawa, Canada

1 INTRODUCTION

Significant attention has been devoted to the study of nanotechnology and nanochemistry in the past quarter century.¹ The most common formation of colloidal nanoparticles has been achieved using bottom-up synthesis accomplished by reducing metal ions (M^{n+}) to their atomic state, M^0 , followed by spontaneous self-assembly. These reactions are generally performed in aqueous or organic solutions using thermal or photochemical methods with chemical reducing agents. The photochemical approach in aqueous environments is the focus of this contribution.

In many of the systems presented here, the reducing species is a free radical capable of donating an electron; in fact, it is very likely that the involvement of free radicals greatly exceeds the number of systems where this mechanistic pathway has been recognized or characterized in the literature. Radical generation plays an active role in the nucleation step; therefore, particle size, dispersity, and morphology can be finely tuned with the proper selection of reducing chemistry and the rate of these processes.

Many radicals show good electron donating properties, and among these, ketyl^{2,3} and α -aminoalkyl radicals^{4,5} are known for their strong reducing properties.⁶ Conveniently, a number of efficient photochemical methods are available for their generation.^{7,8} Once metal atoms are generated in solution, formation of nanoparticles is typically a spontaneous process governed by nucleation and growth periods, with fast radical generation generally favoring smaller monodispersed particles.

Control of synthesis parameters is therefore a challenge every chemist must consider when preparing nanostructures. Furthermore, even having the desirable size and morphology does not ensure particle stability, and thus, a wide range of approaches exist to achieve an acceptable nanoparticle life expectancy. Particularly, many nanoparticle synthetic procedures add stabilizers during the synthesis or shortly after the particles have been prepared. Such stabilizers may include ions, surfactants, thiols, polymers, and a wide range of natural and synthetic biomolecules.

From an applications-type perspective where a “custom” surface coverage is desired, the ideal starting point would be with a “naked” or unprotected nanoparticle, such that the exposed metal surface could be readily available for custom modification.

Figure 1 Normalized absorption spectra for noble metal nanoparticle in aqueous colloidal solutions. [Curves for AuNP and CuNP adapted from an earlier publication.]¹⁰

This contribution concentrates on the photochemical synthesis of noble metal nanoparticles, gold, silver, and copper in aqueous systems. Significant interest in noble metal nanoparticles arises from their optical properties. Noble metal nanoparticles possess strong collective oscillations of electrons in their conduction band and absorb strongly in the visible region. This absorption feature is referred to as the surface plasmon band (SPB), which is the summation of absorption and scattering modes, and shifts to lower frequencies with increased surface polarizability.⁹ For small spherical nanoparticles in colloidal aqueous suspensions, Figure 1 shows typical spectra.¹⁰

Small environmental changes result in SPB shifts related to particle size, particle shape (morphology), interparticle distance, refractive index, and temperature of the medium. New or enhanced absorption at long wavelengths can be due to increase in particle size, decrease in the interparticle distance, or formation of nonspherical morphologies.^{9,11}

2 WHY USE PHOTOCHEMISTRY?

A number of reliable methods to produce noble metal nanoparticles without using light are readily available and well established, particularly in the cases of gold and silver.^{12–14} While traditional approaches to colloidal preparations offer control over particle size and morphology by manipulation of reagent concentration, temperature, and variation

of the experimental protocol (e.g., order of addition of reagents), a photochemical approach offers spatial-temporal resolution, thus providing additional synthetic flexibility. The wavelength, light intensity, and temporal profile of the illumination can also be readily adjusted to facilitate control of size, morphology, and surface properties. Photochemical methods frequently lack the chemical complexity of thermal systems, can operate under milder conditions, and can leave significantly less chemical debris on the nanoparticles as compared with thermal processes.¹⁵

The frequently quoted advantages of photochemical methods, that is, *spatial and temporal control*, are just as applicable to nanoparticle synthesis as they are to conventional (film) photography, where the spatial distribution of light and the duration and timing of the exposure determine the quality of a photograph. Naturally, this advantage will apply to any imaging system, such as lithography.

Temporal control can have a much wider application; even when imaging is not important, the ability to turn the reaction on-and-off will represent a major tool for reaction control.

3 PHOTOCHEMICAL NANOPARTICLE PRECURSORS

What molecular properties are desirable in a precursor for efficient photochemical synthesis of nanoparticles? Clearly, the excited state of this precursor

Figure 2 Jablonski diagram illustrating the photophysics of acetone and its reaction to give products of hydrogen abstraction leading to the ketyl radical. Abstraction is an activated process. The energy values for S_1 and T_1 are 84 and 78 kcal mol⁻¹, respectively. At room temperature $\Phi_{\text{fluorescence}} \leq 0.001$ and $\Phi_{\text{ISC}} \sim 1$.

must be able to generate reducing free radicals. Is this enough?

Let us consider the example of acetone. When excited by ultraviolet light, acetone produces its excited singlet state, which rapidly undergoes inter-system crossing (ISC) to form the triplet state, as shown in the Jablonski diagram of Figure 2.⁸

Acetone displays weak fluorescence and phosphorescence; however, these properties are only exhibited in the absence of oxygen or hydrogen donors.⁸ Both the excited singlet and triplet states are capable of hydrogen abstraction from suitable donors,¹⁶ although in general only abstraction of the triplet state is observed for the rather trivial reason that the short singlet lifetime of the singlet state makes abstraction (or more generally chemical reaction) unlikely. Thus, the acetone triplet state can abstract

hydrogen from 2-propanol⁸ to generate two reducing radicals,³ as shown in Scheme 1.

Despite its favorable triplet reactivity, acetone's performance is limited by several factors. In particular, acetone absorbs light at a rather short wavelength (cutoff is ≤ 330 nm) and with a very modest extinction coefficient.⁸ Consequently, transition metal salts tend to compete for light absorption, thus reducing the efficiency of acetone photolysis. Competition for light absorption also implies that transition metal complexes can be subject to their own photodecomposition.

Furthermore, the lifetime of acetone triplets influences the yield of nanostructures. Acetone triplet lifetime is in the microsecond range^{17,18} and rate constants for hydrogen abstraction are two to four orders of magnitude slower than diffusion-controlled kinetics. The reason why this becomes a serious problem is because many transition metal ions (including the noble metals) are excellent quenchers of excited states (singlet and triplet), with rate constants that approach the diffusion-controlled limit.^{19,20} As a result, many (and probably most) acetone triplets would be quenched before they participate in reactions yielding free radicals, thus limiting the steady state concentration of reductive radicals in solution.

The result of poor absorption properties and quenching by transition metals underlines an inefficient process requiring very long irradiation times (hours). Quite simply when an excited state is quenched by a metal ion, it no longer can yield the desirable reducing free radical. A few representative triplet quenching rate constants by metal ions are given in Table 1.

There are, however, two highly desirable properties of acetone that should not be overlooked. First, all the organic products and reagents in Scheme 1

Scheme 1 Photoreduction of acetone ("*" indicates T_1 state) to yield a ketyl radical. Reaction (2) illustrates electron transfer to a monovalent metal ion which later forms metal nanoparticles (MNP).

Table 1 Rate constants for the quenching of excited triplet states by metal ions in solution at room temperature.^{19–21}

Triplet state	Medium	Ion	k_q (M ⁻¹ s ⁻¹)
Benzophenone	SDS micelles	Ag(I)	4.6×10^9
Azaxanthone	Acetonitrile	Au(I)	2.8×10^9
Azaxanthone	(3 : 1) Water : acetonitrile	Au(III)	1.03×10^{10}
Xanthone	Acetonitrile	Cu(acac) ₂ ^a	8.5×10^9
Benzophenone	Acetonitrile	Cu(acac) ₂ ^a	5.3×10^9

^aacac, acetylacetonate.

are volatile and thus easy to remove once the nanoparticle synthesis is complete. Second, notice that reaction (2) regenerates the reagent, that is, acetone. In this sense, the mechanism of Scheme 1 is a photocatalytic process.

While the “recipe” outlined in the following paradigm refers to ketyl radicals, the same concepts are applicable to other types of reducing radicals, including α -aminoalkyl radicals. Both these species can be viewed as caged electrons, ready to deliver when a suitable acceptor is available. We note that beyond the electron acceptor, a proton acceptor is also required; in water, this is not a problem, but in organic solvents, the scarcity of proton acceptors can hinder kinetics and efficiency of reaction.²²

4 A PARADIGM FOR THE SELECTION OF PHOTOCHEMICAL NANOPARTICLE PRECURSORS

The selection of a precursor for the photochemical synthesis of nanoparticles is similar to the selection of a photosensitizer for many other applications,⁸ although a few parameters reflecting the properties of transition metals and the resulting nanoparticles affect the details of the selection, that is,

1. Precursor absorbance at relatively long wavelength, such as the UVA region, for example, ~ 360 nm, where any absorption of the metal complex would interfere less.
2. Precursor chromophore with a high extinction coefficient, such that millimolar solutions can absorb a large fraction of the light ($\epsilon_{\text{UVA}} > 1000 \text{ M}^{-1} \text{ cm}^{-1}$).
3. High quantum yield of radical formation is an asset. Ideally, $\phi_{\text{decomposition}} > 0.1$.
4. Radical production via fast unimolecular cleavage, such as some examples of the Norrish type

I reaction.⁷ Fast generation of reducing radicals (that also requires point 3) enables a high steady state concentration and a short nucleation period.

5. If radical production must involve a bimolecular reaction, select a highly reactive precursor according to points 1–3, and couple with an exceptional hydrogen donor ($k_H \sim 10^7 \text{ M}^{-1} \text{ s}^{-1}$ or greater), or use segregation techniques (described later). Bimolecular reactions should be avoided,²⁰ particularly if unprotected particles are preferred.
6. The radical precursor must be soluble in the reaction media under typical colloidal synthesis conditions at millimolar concentrations.
7. It is best if the precursor and any reaction byproducts are minimized, by way of a simple, clean synthesis or volatile reagents/products that can be removed following nanoparticle synthesis.
8. For biological applications select precursors of low toxicity.

4.1 Bimolecular Routes to Photochemical Nanoparticle Synthesis

To further elaborate on points 4 and 5 above, in order to minimize transition metal quenching of excited states by transition metals, one must separate the radical formation process from quenching events. Such prevention can be achieved with spatial-temporal techniques. Time separation can be achieved by selecting a precursor with a short excited state lifetime, so that the metal ions (typically millimolar) cannot quench a significant fraction of the excited states.^{19,23,24} The efficiency of excited state survival (S_{surv}) can be estimated according to the following equation:

$$S_{\text{surv}} = \frac{\tau^{-1}}{\tau^{-1} + k_q[Q]} \quad (4)$$

where S_{surv} is the fraction of triplets surviving quenching, τ the triplet lifetime in the absence of quenchers, and $[Q]$ the quencher concentration. In our systems $[Q] = [M^{n+}]$.

If a long excited state lifetime of the precursor is unavoidable (i.e., >100 ns) then spatial separation is necessary; this is common for bimolecular systems. A typical strategy is to physically segregate the radical generation environment from the reducing environment that can be easily achieved with micelles, where transition metal ions and their salts can be expected to preferentially locate in the aqueous phase.^{19,20,25} In contrast, it is easy to design a system where organic precursors (e.g., benzophenone or 1-azaxanthone) have a preference for the organic microphase, such as the micelle, effectively protecting radical precursors from undesirable transition metal quenching. Interestingly, in the case of ketyl radicals, the presence of an OH group in the radical makes it sufficiently hydrophilic for it to exit the micelle and undergo the desirable electron transfer reaction to reduce the metal ions.¹⁷ This bimolecular approach and necessary segregation of events have been executed in a number of micellar and polymer systems.

Among hydrogen donors, 1,4-cyclohexadiene has been a favorite, given its excellent H-donor properties and high volatility.^{19,20}

4.2 Unimolecular Routes to Photochemical Nanoparticle Synthesis

It is time to describe the radical precursor that has been a favorite in our Ottawa laboratories,^{23,26–28} Irgacure-2959 (I-2959) a molecule originally supplied to us as a gift by CIBA Specialty Chemicals. Scheme 2 illustrates the reaction mechanism in the case of Ag^+ .²⁹

What makes I-2959 such a desirable molecule? It complies with all the requirements in our paradigm, except 7, since one of the products (see reaction 8) is not very volatile. Conveniently, however, the benzoyl radical is oxidized to form the acid, 4-hydroxyethoxybenzoic acid (HEBA), under ambient conditions and contributes to provide particle stability and longevity through interactions with the particle surface. Furthermore, the amphiphilic properties of I-2959 have allowed its use in a wide range of solvents at the millimolar concentrations required for this work. Thus, it is possible to employ solvents such as water, tetrahydrofuran (THF), toluene,²⁸ and various micellar solutions.¹⁹

The photochemistry of I-2959 has been studied by Turro and coworkers,⁷ who established that Norrish type I cleavage occurs with a triplet lifetime of 11 ns and a quantum yield of 0.29 in acetonitrile. These properties are not only favorable for nanoparticle synthesis but are in fact also remarkable, given that

Scheme 2 Mechanism for photochemical nanoparticle synthesis (illustrated with silver) initiated by photodecomposition of I-2959. Reaction (5) is an example of Norrish type I cleavage. HEBA is a byproduct of the reaction formed in reaction (8), which probably includes radical trapping by oxygen,³⁰ formation of the peracid and eventual reduction to give HEBA.

Scheme 3 Multiple ketyl reductions and ion disproportionations lead to atomic gold, from which AuNPs are formed.

oxygen substitution at the 4 position must give the triplet state of I-2959 significant π, π^* character, which normally confers the excited state reduced reactivity in Norrish type I and II reactions.³¹

Our first application of I-2959 was in the production of gold nanoparticles (AuNPs), a study that stimulated much work within our Ottawa laboratories.²³ Scheme 3 simplifies the rather complex chemistry involved in the reduction of AuCl_4^- , the most common precursor for gold nanostructures. For convenience, we write the initial gold species as Au^{3+} , although we note that there are systems where the negative charge in AuCl_4^- can play an important role.²⁷

The simplicity of Scheme 2, where Ag^+ requires a single electron for reduction to its metallic form, contrasts with the case of Au^{3+} where three electrons are required. Reaction (9) forms Au(II), which disproportionates rapidly,³² as shown in reaction (10).¹⁹ Au(I) is then reduced by another ketyl radical (reaction 11) to generate atomic gold. Above a threshold concentration of gold atoms, nanoparticle growth is established. Table 2 shows representative rate constants for the reaction of

some ketyl radicals with metal ions. Table 2 also includes values for O_2 , given that this is a common competitive process.

In addition to I-2959, the precursor I-907 has also proven useful, known for its generation of α -amino alkyl radicals, and a valuable back-up when ketyl radicals do not reduce M^+ with appropriate kinetics, Scheme 4.

It is of course the redox properties of the radicals that make them so useful for nanoparticle synthesis. For the 2-hydroxypropyl ketyl radical in acetonitrile $E^0(\text{CH}_3)_2\text{CO}, \text{H}^+ / (\text{CH}_3)_2\text{C}^+\text{OH} = -0.37 \text{ V}$ versus normal hydrogen electrode (NHE), while for the $(\text{CH}_3)_2\text{NC}^+(\text{CH}_3)_2$ (a model for the isopropylmorpholino radical) in acetonitrile, $E^0 \sim -1.47 \text{ V}$ versus NHE.^{6,35,36}

There are several reasons why I-907 has not replaced I-2959 unless this favored precursor becomes ineffective. In particular, we frequently try to prepare nanoparticles with minimum interference from N, P, and S ligands,³⁷ clearly I-907 fails to achieve this. In addition, we have been concerned that the presence of free amines (*N*-isopropylmorpholine $\text{p}K_a = 9.3$) in the radicals precursor (i.e., I-907) could lead to dark generation of nanoparticles under basic conditions, since amines themselves are good reducing agents. This was not a significant problem under mildly acidic reaction conditions, although with hindsight it may reflect that I-907 was normally tested for systems that proved more reluctant to I-2959 photoreduction.

4.3 Initiator-Free Photochemical Nanoparticle Synthesis

The term *initiator-free* is used to describe systems where a specific photoinitiator is not added to the reaction mixture, but rather, that take advantage of

Table 2 Rate constants for the reaction of ketyl radicals with metal ions in solution at room temperature.^{19,33,34}

Radical	Scavenger	Conditions	Rate constant ($\text{M}^{-1} \text{s}^{-1}$)
Ketyl from acetone	Oxygen	Water	4.5×10^9
Ketyl from benzophenone	Au(I)	Acetonitrile	2.5×10^8
Ketyl from benzophenone	Au(III)	Acetonitrile	9.9×10^8
Ketyl from acetone	Cu(II)	Water	5×10^7
Ketyl from acetone	Cu(I) ^a	Water	5×10^9

^aThe reaction involves complex addition chemistry.

Scheme 4 Photodecomposition of Irgacure-907 leads to the formation of morpholine-derived α -aminoalkyl radicals, which can reduce many metallic ions to their atomic form.

Scheme 5 Photolysis of AuCl_4^- yields chlorine atoms that readily abstract hydrogen from a wide range of hydrogen donors.

photochemical characteristics already present in the metal precursor structure. Such opportunistic use of the metal precursor limits the amount of chemical debris retained by the nanoparticles. Here, the key strategy is that any other molecules that need to be added, such as hydrogen donors (and the resulting products) must be volatile, so that they can be readily removed once the synthesis is complete.

For the purpose of illustrating this strategy, we use the case of aqueous AuCl_4^- , a system that was recently studied in our laboratories.³⁸ Here, the key reaction is the photolysis of AuCl_4^- that yields chlorine atoms, in themselves powerful hydrogen abstractors³⁹ and thus capable of generating secondary free radicals, as illustrated in Scheme 5.

Reaction (16) in Scheme 5 can involve a wide range of H-donors, but it is important to select those where the resulting radical, $\text{A}^\bullet$, has appreciable reducing properties. A number of molecules examined in our laboratories³⁸ are shown in Scheme 6.

The radical in reaction (b) of Scheme 6 is of course the same as in equation (6) in Scheme 2, but in reaction (b), the 2-hydroxypropyl radical was produced from 2-propanol, and thus avoiding the generation of nonvolatile products. There is, however, a need for additional stabilizer if small, spherical nanoparticles are desired. Importantly, all

the donors in Scheme 6 have negligible absorption at ~ 350 nm, the preferred photolysis wavelength used for nanoparticle synthesis. Their spectral characteristics ensure that the reduction reaction is not dependent on excitation of the ligand-to-metal charge transfer (LMCT) of the metal complex.

Perhaps the most interesting molecule in Scheme 6 is hydrogen peroxide, used as a reducing agent in these applications. Here, the products are oxygen and water and is mediated by the $\text{HOO}^\bullet$ radical that donates an electron to Au(III) . The reaction then proceeds with the standard reduction steps until Au(0) is formed. Interestingly, the $\text{Au(I)} \rightarrow \text{Au(0)}$ step is catalyzed by AuNP , and thus as soon as the formation of nanoparticles commences, the reaction accelerates and quickly reaches completion.

The methodologies and references as they relate to the strategies of Scheme 6 are not meant to be exhaustive, but rather to emphasize work in the Ottawa laboratories. A noteworthy synthesis on AgNP was reported by Giuffrida *et al.*,⁴⁰ who showed that AgNP can be produced thermally from silver acetylacetonate; AgNP can also be obtained in an accelerated process by photolysis of the same precursor.

The strategies presented in this section offer the possibility to produce noble metal nanostructures employing clean technologies, but they do not guarantee that the desired shape or size will be obtained nor do they ensure the desirable long-term stability needed for many applications. Users of these methodologies need to adapt them incorporating the desired surface covering agents so as to prepare nanostructures that meet their requirements.

Scheme 6 Various volatile H-donors (A–H) can be used to generate free radicals that can donate an electron to appropriate acceptors, in particular, metal ions. In all cases, a proton is released that requires a suitable acceptor. In aqueous systems, water plays this role.

5 FACTORS THAT CONTROL THE OUTCOME OF NANOPARTICLE PHOTOCHEMICAL SYNTHESIS

Trying to list all factors that could influence the outcome of nanoparticle photochemical synthesis is an impossible task. Thus, this section deals with main factors that are either well known or that reflect our experience at the University of Ottawa. Each subsection deals with one of these parameters.

5.1 Light Intensity

As a general rule, faster reducing radical generation leads to shorter nucleation periods and thus smaller nanoparticles, as outlined in Scheme 1. In the case of photochemical processes, this also implies that smaller particles will be obtained at the higher light intensities.²³ Unfortunately, the relation between reciprocal particle size (diameter^{-1}) and dose (or irradiance) is not linear, and thus desirable very small particles may fall in a range of light intensities that is not achievable with conventional light sources.

Exposure to pulsed light sources, such as lasers, is not described in this contribution as a methodology for nanoparticle synthesis, although it is sometimes employed,^{41–43} and nanoparticle laser ablation can also be used as a method to modify nanoparticles.^{44–48}

5.2 Arrested Growth

If a given photochemical synthesis protocol produces nanoparticles that are too large for a planned application, it is possible to arrest the particle growth by adding small concentrations of stabilizing agents prior or during the synthesis. Given our preference for unprotected materials, we have concentrated on charge-stabilizing ligands and used compounds that do not lead to surface covalent bonds; for example, we avoid sulfur compounds. In the case of AgNP described herein, citrate salts have proven convenient as a way of limiting particle growth to 3–4 nm.^{29,49} Note that while citrate is frequently used as part of a reducing formulation, in this case, it is simply a capping ligand, since fast and efficient reduction is achieved by photochemical means, such as the use of I-2959 illustrated in Scheme 2.

Scheme 7 Mechanism for the synthesis of CuNP in aqueous solutions containing chloride. [For mechanistic details, see the original publication from which the mechanism shown was adapted.]²⁴

5.3 Counterion Influence

Every component present at the time of particle synthesis can influence nanoparticle size and morphology through ionic effects. For example, ionic strength is an important factor. However, there are systems where ionic components can be critical. This is the case of CuNP, where halides, in particular chloride, can determine the rate of particle formation as well as their polydispersity.²⁴ The complex mechanism involved is presented in Scheme 7. Different counterions (especially halides) and surfactants can “tune” the morphology and size of the nanostructures formed. In aqueous solutions, chloride ions catalyze the disproportionation that mediates the $\text{Cu(I)} \rightarrow \text{Cu(0)} \rightarrow \text{CuNP}$ conversion.

The rationale for the proposal of the mechanism of Scheme 7 can be found in the original publication.²⁴ As a consequence of these reactions, CuCl_2 yields highly polydispersed particles rapidly, while when using CuSO_4 , the reactions are slower, but the CuNPs are more monodisperse.

5.4 Atmosphere

Given that many of our synthesis procedures involve carbon-centered radicals, one could anticipate that

any oxygen in the reaction atmosphere could have an adverse effect on nanoparticle synthesis. This is in fact not always the case. AuNP prepared from I-2959, for example, are most stable when prepared under air.^{19,23} While initially puzzled by this result, we have identified HEBA as a photoproduct (Scheme 2), that contributes to particle stabilization. Most likely, formation of HEBA is mediated by the corresponding peracid. Note also that while O_2 will trap some ketyl radicals (reaction 17), the $\text{HOO}^\bullet$ radicals produced are also capable of gold reductions, as indicated in Scheme 6. Note that the generation of acid in reaction (6) and related processes, systematically lead to particle formation in acid media (thus making $\text{HOO}^\bullet$, rather than $\text{O}_2^{\bullet-}$ the dominant species). Benzoyl³⁰ and acetone ketyl radicals³³ react with oxygen with reported rate constants of $1.8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and $4.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, respectively.

Excessive oxygen (as in pure O_2 atmosphere) can be employed as a tool to delay AuNP formation and thus further control particle size and shape.

The formation of unprotected AgNP by reduction with ketyl radicals results in unstable colloids,

whether or not in the presence of oxygen. However, when kept in a reducing environment, by stabilizing with citrate ions, small silver nanoparticles (3–4 nm) can be generated with or without the presence of oxygen without a detectable effect of oxygen on final particle size or reaction rate. These solutions of citrate-stabilized AgNP are stable indefinitely under air when protected from light to avoid shape transformations (*vide infra*).⁴⁹ Solutions using I-2959 to form AgNP are, however, most commonly oxygen free to ensure maximum efficiency of the reducing precursor and thus a rapid nucleation of AgNP.

In the case of CuNP, these particles are very sensitive to air oxidation and oxidize readily to form Cu^{2+} in aqueous solution once exposed to air. The oxidation reaction typically takes 1–2 h. Thus, it is not possible to prepare and preserve the CuNP under aerated conditions.

5.5 Stoichiometry

The reaction stoichiometry is primarily governed by the number of electrons required to reduce the metal ions, for example, in the case of Au(III), three electrons are needed. Thus, typically when we employ I-2959, we prepare AuNP using 0.3¹⁹ or 0.33 mM²³ AuCl_4^- that would require 0.9–1.0 mM of I-2959; we normally use 1 mM, that is, stoichiometric or allowing for a slight excess of radical generator. For Cu(II) and Ag(I), the anticipated 2:1 and 1:1 stoichiometries work well.

In the case of AuNP, deficient stoichiometry (less reductant than needed for a stoichiometric ratio) tends to yield larger particles with average sizes around 70 nm. These particles are less stable compared to the ones prepared in a stoichiometry ratio as well as more polydisperse.

5.6 *In Situ* Stabilization

While the emphasis of our work has been on the synthesis of relatively unprotected nanoparticles, the methodologies presented here lend themselves to adaptation for *in situ* stabilization. The possibilities in this area are numerous and impossible to cover in this contribution. An important consideration

must be that ligands and stabilizers present during synthesis should not be effective radical traps that would likely interfere with the nanoparticle-forming free radical reactions discussed in this article.

We note that in the case of micellar solutions, some of the solubility rules mentioned earlier are relaxed, and it is possible to employ a wider range of initiators, such as conventional benzoin with poor aqueous solubility.¹⁹

5.7 Storage

AuNP have shown excellent stability (+5 years) when stored in plastic containers; they are also stable to ambient atmosphere. AuNP prepared in the charge-stabilized manner utilizing I-2959 have found, however, limited stability in glass containers (~1 day) and this is attributed to the favorable interaction with the negatively charged silica surface. In particular, instability is accompanied by a red shift of the SPB, suggesting particle agglomeration.

Very small (~3 nm) AgNP stores better in glass than plastic unless there is light, where some of the AgNP tend to deposit onto the glass. AgNP are indefinitely stable under air.

Owing to oxidation, as previously mentioned, CuNP storage is limited to an oxygen-free atmosphere such as in a glovebox or to the reservoir they were synthesized as long as oxygen does not diffuse into the system.

6 POSTSYNTHESIS PHOTOCHEMICAL MODIFICATION OF NANOSTRUCTURES

The range of modifications is so diverse that only a few cases can be included in this section. The examples that follow have been selected among those that have interested our Ottawa group.

6.1 Seeded Growth

The unprotected nature of photochemically generated aqueous nanoparticles is an asset for additional growth through seed-mediated processes. Addition of photochemically generated AuNP to a dilute

Table 3 Characteristics of silver nanostructures obtained by LED irradiation of ~3 nm AgNP seeds.⁴⁹

λ_{LED}	Comments	Spectral data	Solution image	Spectrum ^a
N/A	3-nm spherical seeds	397 nm		
405 nm	Spheres, 26-h exposure	415 nm		
455 nm	Decahedra, 3-h exposure	480 nm		
505 nm	Predominantly hexagonal plates, 20-h exposure	540 nm		

(continued overleaf)

Table 3 (continued)

λ_{LED}	Comments	Spectral data	Solution image	Spectrum ^a
590/627 nm	Mostly triangular plates, long exposure >100 h	690 nm		
720 nm	Rods and thin plates, 1-week exposure	Near IR		

^a All plots correspond to exactly the same total silver concentration.

growth solution of the metal salt and mild reducing agent results in reduction of the metal salt via particle-mediated catalysis.¹⁰ The choice of mild reducing conditions is essential to minimize the generation of new AuNP, termed *secondary nucleation*. Ascorbic acid and hydroxylamine hydrochloride have been common choices in our laboratory for the seeding of AgNP and AuNP, respectively. Similar approaches were devised by Brown *et al.*⁵⁰ with citrate-mediated growth of AuNP seeds. Given that the particle surface itself is a site of reduction, the growth behavior involves the deposition of new layers of atoms; these form faster when more reducing agent is present, as the concentration of HAuCl₄ is held constant. Additionally, the lesser the concentration of seed added, the larger particles result from seeded growth.

In the case of AgNP, we have used ascorbic acid for growth of particles designed for Raman enhancement applications.²⁹

6.2 Light-Induced Morphology and Size Changes

Our research has shown that small AgNP seeds (about 3 nm in diameter) can be used to generate a range of morphologies (and a rainbow of particle colors) when irradiated with monochromatic light, which in our work was generated by a variety of inexpensive light-emitting diode (LEDs).⁴⁹ This simple methodology can be used to generate different morphologies while maintaining the chemical nature of the surface coverage. Table 3 summarizes the results obtained in these systems.⁴⁹

We have wondered whether the LED-induced changes shown in Table 2 could be reversed. We have observed that nanoparticle laser ablation can be used to return spherical AgNP, although the monodispersity of the original particles (or seeds) is not restored through the ablative process.¹⁰

Similar strategies may work with other metal nanoparticles, although to date these strategies have not been explored in our group.

6.3 Surface Chemical Modification

All the strategies for surface modification that are frequently employed with thermally produced nanoparticles can also be applied to photochemically produced ones; the unprotected nature of the particles described in this article frequently makes surface modification a facile process, and for example reaction of AgNP with thiols can occur in a few minutes. Similarly, passivation of the AuNP surface with a variety of ligands such as thiols, amines, biomolecules, or a silica shell has been achieved for subsequent application.

7 BEYOND AQUEOUS GOLD, SILVER, AND COPPER MONOMETALLIC NANOPARTICLES

The emphasis on noble metal nanoparticles in aqueous media described here provides a template to illustrate how simple free radical photoinitiators can be employed for the facile synthesis of metal nanoparticles, reflecting both the rich information available on these systems, as well as the work within our own laboratories. Similar strategies have been employed to prepare magnetic cobalt nanoparticles (CoNP) as well as platinum (PtNP) and ruthenium (RuNP) particles¹⁰ in nonaqueous systems; these last two materials are of interest for their catalytic properties. In addition, similar methodologies can be used for the synthesis of highly fluorescent silver nanoparticles AgFNP in nonpolar media, such as in THF and toluene; the fluorescence has been attributed to small silver clusters (including Ag₂) on the surface of small AgNP.²⁸ A separate study demonstrated that the dimerization of silver atoms ($2\text{Ag}^0 \rightarrow \text{Ag}_2$) is a diffusion-controlled reaction in organic media.²²

In a system currently under investigation, nanoparticles (e.g., AgNP) can be produced in a protein composite.

While all our examples above deal with monometallic particles, photochemical techniques

can also be employed to prepare bimetallic particles; we have demonstrated these processes for the Au–Ag system.^{26,27} These particles assemble according to the redox characteristics of the pair; thus, gold tends to reduce first to form the particle core, followed by silver reduction with plating to form a silver shell. True alloys can also be prepared by taking advantage of coulombic interactions involving Ag⁺ and AuCl₄[−].²⁷

8 CONCLUSION

Radical-mediated photochemical synthesis of metal nanoparticles offers remarkable flexibility in the synthesis of these materials. The paradigm presented here should be applicable to nanostructures made from many metals, beyond the noble metals used in our examples. Furthermore, size, morphology, and surface coverage are frequently “tunable.” The challenge is to develop new applications for these materials, such as biomedical uses, markers, sensors, electronics, photonics, and catalysis. The next decade will no doubt see further developments in these areas and in many more that we are yet to imagine.

ACKNOWLEDGMENTS

Thanks are due to the Natural Sciences and Engineering Research Council of Canada for ongoing support. Many coworkers from Ottawa have contributed to our learning about metal nanostructures, and their names appear in the references. Authors of this contribution have made detailed contributions to the synthesis of AuNP, AgNP, and CuNP.

The History of Free Radical Chemistry

Thomas T. Tidwell

Department of Chemistry, University of Toronto, Toronto, Ontario, Canada

1 INTRODUCTION

From the beginning of the nineteenth century, there were premonitions of the existence of free radicals,^{1–10} but only in 1900 was convincing evidence for these species found with Gomberg's discovery of the triphenylmethyl radical,^{11,12} a highly stabilized example. This was followed three decades later by Paneth's identification of simple alkyl radicals,^{13–15} which are a larger and more significant class, and are very reactive and short-lived. At the time, these discoveries were not based upon direct observation, as the yellow color of the tri-phenylmethyl radical was overlooked,¹⁶ and alkyl radicals are invisible. The originality of these discoveries is reflected by the fact that, while both were immediately widely noted, the initial triphenylmethyl radical discovery in particular was also met with disbelief. Neither was honored with the ultimate accolade of great discoveries, the Nobel Prize, although numerous later advances in free-radical chemistry, which were built on these discoveries, have achieved this distinction. The uniqueness of the original discoveries meant that their true significance could not be fully appreciated at the time.^{16–21}

This historical summary attempts to note significant new discoveries in free-radical chemistry in a generally chronological order, with inclusion of recent developments in some examples to illustrate advancements in long-established areas of study. The emphasis is on carbon free radicals, but basic developments in radical chemistry that profoundly affected these studies are included. The first third of

the twentieth century was marked by rapid exploration of the types of conjugated radicals that could be identified, and different ways for their generation. Kinetic studies of reactive radicals, particularly the halogens, were also explored. The experiments of Paneth then focused attention on the study of non-conjugated aliphatic radicals, and, with the broad outlines of the field established thereafter, studies have concentrated on new types of free radicals and new applications, and there has been a continuous development of new and useful chemistry that shows no sign of slowing; but the newer work is mostly beyond the scope of this survey. Many individuals participated in the advance of free-radical chemistry, and some of the most prominent original contributors are recognized where possible, but the constraints of space preclude mentioning many others who also made important discoveries. This article provides an overview of the development of many fundamentals of free radicals, while the definitive articles in this encyclopedia on the various topics provided by leaders in their study describe the current state of knowledge.

2 DISCOVERY OF THE TRIPHENYLMETHYL RADICAL

2.1 Free Radicals Before Gomberg

The early history of free radicals in organic chemistry prior to 1900 has been frequently reviewed,^{1–3} and is only briefly noted here, and developments

in the twentieth century have already been extensively summarized.^{16–21} While the term “radical” dates to the late eighteenth century, the existence of alkyl radicals gained new support in 1849, based both on the work of Kolbe,⁴ who reported the electrolytic decarboxylation of potassium acetate apparently forming free radicals such as “methyl” (CH₃), and of Frankland,⁵ who reported the formation of “ethyl” (C₂H₅) from the reaction of ethyl iodide with zinc. However, the development of valence theory shortly thereafter, particularly the concept of the tetravalency of carbon, led to the recognition that these “radicals” were dimers, and caused the general abandonment of free radicals as organic intermediates.

Downes and Blunt in 1879 reported that hydrogen peroxide in solution was destroyed by sunlight to form *two groupings* of the radical HO.⁶ They further speculated the same phenomenon occurred with chlorine, and stated: “We believe that the tendency of sunlight is to dissociate (or ‘weaken the internal bonds’ between). . . and thus to promote their combining energy.” This prescient interpretation was however not applied to hydroxyl radical reactivity with organic compounds, and is not mentioned in other reviews of the history of organic free radicals,^{1–3,16–20} or apparently not even previously cited by a chemist.

Even with this great missed opportunity, the concept did not disappear, and, in 1891, Crum Brown and Walker reintroduced the idea of electrolysis as involving radicals, (1),⁷ while Nef in 1897⁸ formulated a theory of organic reactivity with a major role for divalent carbon. Thus the possible existence of organic free radicals was waiting to be recognized, but the discovery did not result from a deliberate search, and recognition came from the need to explain new and unexpected experimental facts.

2.2 Discovery of the Triphenylmethyl Radical

The understanding of the structure of organic compounds had evolved during the nineteenth century but the concept of reactive intermediates was still incomplete, and reaction mechanisms were poorly understood. In a prelude to the discovery of free radicals, Gomberg in 1897 used

phenylazotriphenylmethane in the classic preparation of tetraphenylmethane (2), (2), a process now understood to result from coupling of the triphenylmethyl radical **1** and a phenyl radical, but he did not speculate about the source of the product.^{9,10}

Then, in 1900, Gomberg made the bold announcement of the formation of the stable and persistent free radical triphenylmethyl **1** by reaction of tri-phenylmethyl chloride with silver or zinc metal giving a colored solution, with its radical character shown by the facile reaction with oxygen forming the peroxide **3** (3).^{11,12} This discovery was published in both German and English, and attracted the immediate attention of the world chemical community.^{16–21} There was also immediate skepticism, notably even in 1901: Norris presented a rebuttal entitled *On the Non-Existence of Trivalent Carbon*.^{22,23} This led to much further study with considerable controversy over the next decade, and the structure of **1** was finally settled by Wilhelm Schlenk and coworkers in 1910 when they obtained tris(4-biphenyl)methyl (**4**) as a deeply colored solid that was almost completely dissociated in solution, which confirmed the existence of **1**.²⁴

Removal of the solvent from the preparation of triphenylmethyl gave a colorless solid product with a dimeric structure for which the symmetrical head-to-head structure **5** as well as the unsymmetrical structure **6** (head-to-tail, Jacobson structure)²⁵ and **7** (tail-to-tail, Heintschel structure)^{26,27} were

given serious consideration. The dimer underwent dissociation in solution, and its properties were often hard to interpret, and the wrong structure, namely the head-to-head structure **5**, became accepted for more than half a century, as has been described by McBride.¹⁶ Only in 1968 was this finally corrected to the unsymmetrical structure **6** based on spectroscopic data by Lankamp, Nauta, and MacLean,²⁸ who made the surprising, but in retrospect completely predictable, finding that the triphenylmethyl dimer had the head-to-tail structure.

In retrospect,¹⁶ not only was the original evidence for the misidentified structure of the dimer rather flimsy, but techniques such as nuclear magnetic resonance (NMR), infrared (IR), and ultraviolet (UV) were also widely available that would have permitted correction of this structure well before 1968. As described below, a variety of head-to-head hexaphenylethane structures in which the steric hindrance in the head-to-head structure **5** is circumvented have subsequently been characterized.

The preparation and identification of the stable triphenylmethyl radical was one of the most significant chemical discoveries of the time but, as already noted, was not honored by the award of the Nobel Prize. As revealed by the investigation by Lennart Ebersson^{18,19} in the Nobel archives, Gomberg was repeatedly nominated for the award, but due to a series of unfortunate circumstances the nominations were not accepted. Despite Gomberg's confident assertion in his first paper that he had proof of the existence of the radical, there was later some equivocation, and some contrary opinions, which were enough for the Nobel Committee not to approve the award. Initially, the existence of the radical in equilibrium with the dimer seemed questionable, but with the later preparation of the tris(4-biphenyl)methyl radical **4** as a stable solid the uncertainty vanished.²⁴ However, subsequent

nominations were unsuccessful either because both Gomberg and Schlenk were not nominated in the same year, or because too much time had elapsed since the initial discovery. Even in 1940, Gomberg's name was still put forward, but without success. Gomberg's discovery was a clearly momentous discovery by a single individual, but, although well recognized by posterity, he did not receive the ultimate accolade he deserved.

2.3 Bis(triphenylmethyl) Peroxide

The reaction of the triphenylmethyl radical with oxygen to form the peroxide **3** discovered by Gomberg in 1900 as shown in (3) was a persuasive piece of evidence for the radical structure **1**,^{11,12} and the affinity of radicals for oxygen became known as one of their defining characteristics. As pointed out by McBride,¹⁶ Gomberg did not originally mention the color of the solution containing the radical, but in 1908 Schmidlin²⁹ reported that addition of O₂ to **1** discharged the radical color, and later the formation of an initial peroxy radical **8** was shown to be reversible (4).³⁰

Just as for the triphenylmethyl radical dimer, there are three plausible structures for the peroxide corresponding to the proposals for the radical dimer: namely, head-to-head (**3**), head-to-tail (**9**), and tail-to-tail (**10**). The head-to-head structure **3** was correctly identified, and substituted derivatives of **9** and **10** were later prepared. Thus the tris(2,6-dimethoxyphenyl)methyl radical **11**³¹ was crystallized and found^{32,33} to have a structure with two of the aryl rings twisted out the plane of the central carbon by 61°, while the third was almost coplanar with an 11° twist angle. This radical reacts slowly with oxygen and did not dimerize, but reaction of **11** and of the bis(2,6-dimethoxyphenyl)-phenylmethyl radical (**12**) in solution in the presence of air resulted in crystallization of the substituted Heintschel and Jacobson peroxides **13** and **14**, respectively, with the structures proven by NMR, and X-ray, respectively.^{32,33}

In contrast to **11**, the dimer of sesquixanthrydryl radical **15** was undissociated as a solid and gave weak ESR signals in solution.³¹ The radical **16** with only two oxygen bridges was quite sensitive to oxygen and was extensively dissociated in the solid state, and the 2,6-hydrogens caused twisting out of the plane.^{31,34} The solid dimer of **15** is an authentic hexaarylethane, with a central C–C bond length of 1.63 Å as measured by X-ray.^{34–36}

2.4 Hexaarylethanes

Authentic hexaphenylethane molecules with structures determined by X-ray include **17**, which is restricted from forming a head-to-tail dimer by the bulky substituents, with a central C–C bond length of 1.67(3) Å.³⁷ A different type of hexaphenylethane derivative is typified by **18**, which was already prepared in 1933 for R = H³⁸ and has the central bond constrained by its intramolecular character. The central C–C bond for **18** (R = MeO) was measured as 1.670(3) Å,³⁹ and related examples with similar intramolecular constriction have bond lengths that are even longer.^{40,41}

Preparation of a bis(diphenylpentafulvene) iron complex was reported, for which the structure was considered as either the bis(radical) **19a** or the bis(fulvene) **19b**.⁴² The fact that the X-ray-determined and calculated structure showed the exocyclic groups on the same side of the molecule was taken as favoring the diradical structure, with some attraction between the two radical

sites.⁴³ Computational studies agreed with this conclusion, and indicated that the diradical was a singlet.⁴⁴

2.5 Other Routes to Triphenylmethyl Radicals

Wieland *et al.* in 1922⁴⁵ showed that $\text{Ph}_3\text{C}^\bullet$ (**1**) was formed in the decomposition of phenyl-azotriphenylmethane, and proposed that intermediate phenyl radicals were formed as well (2). Triphenylmethyl radicals are also generated thermally from the perester **20** even at 25 °C (5),⁴⁶ and at much higher temperature also form from the significantly less reactive triphenylacetoxyl *N*-2,2,6,6-tetramethylpiperidine **21** (6).⁴⁷ Reactivity studies demonstrated that both **20** and **21** decompose thermally with concerted two-bond cleavage forming triphenylmethyl radicals **1** and carbon dioxide. A variety of other dissociations of triarylmethyl (trityl)-substituted compounds have been reported to generate triarylmethyl radicals.⁴⁸

A novel route for the generation of triaryl-methyl radicals was by reaction of 1-(haloalkenyl)

-2-allenylbenzenes **22** in tetrahydrofuran (THF) at room temperature in the presence of mercury, resulting in cyclization to 2-naphthyldiphenylmethyl radical **23**, (7), as detected by electron paramagnetic resonance (EPR).⁴⁹ The radical formed a head-to-tail dimer involving the phenyl group, and was captured by oxygen to give the peroxide **24**.⁴⁹ Related ene-yne cyclizations have been examined, including a route to a di(radical) intermediate leading to **25** (8).^{50,51}

2.6 Properties of Triphenylmethyl Radicals

The theoretical basis for the understanding of free radicals was first provided by G. N. Lewis in 1916.^{52,53} His clear recognition of the electron-pair bond and the possibility of odd electron systems was heavily influenced by the work of pioneers such as Gomberg, Schlenk, and Wieland, who had shown remarkable prescience in formulating free-radical structures without, however, using the principles of electron-pair bonding. The theoretical study of the triphenylmethyl radical was later provided by Erich Hückel⁵⁴ at the 1933 Faraday conference on free radicals, which brought together many of the pioneers in the study of radicals.

With the advent of spectroscopic methods, particularly ESR and electron–nuclear double resonance (ENDOR) measurements,⁵⁵ the study of triphenylmethyl and other triarylmethyl radicals has been greatly facilitated, and the assignment of free-radical structures can usually be made with certainty.

3 ALIPHATIC FREE RADICALS AND DIRADICALS

3.1 The Discovery of Aliphatic Free Radicals

Gomberg's discovery and his subsequent work and that of the many others who joined in provided good evidence for the existence of stabilized arylmethyl radicals, but there was still skepticism regarding simple aliphatic radicals such as methyl and ethyl. The modern history of these species had begun with the suggestions of Crum Brown, (1),⁷ but further evidence for these was not forthcoming, despite the great interest in the study of aryl-substituted radicals.

Proof of the existence of aliphatic radicals was, however, unexpectedly provided, inspired by the method pioneered by Bonhoeffer⁵⁶ for showing the generation of atomic hydrogen. Beginning in 1929, Paneth and his coworkers adapted this technique and, in work that paralleled that of

Gomberg, provided a new conceptual framework for the remainder of the twentieth century and beyond.^{13–15} In their classic experiments, a metal organic compound such as tetramethyllead was passed through a hot zone in a glass tube and found to deposit a metallic mirror. When the gases from this procedure passed over a similar metal mirror in a cold section of the tube, the mirror was removed and tetramethyllead was reformed (Figure 1). This demonstrated the formation of methyl radicals in the hot zone where the mirror was laid down, followed by regeneration of the organometallic compound by reaction of the methyl radicals with the cold mirror (9). However, just as in the case of Gomberg's discovery, this paradigm shift initiated by Paneth was not recognized by the Nobel Prize.

This technique was promptly extended by F. O. Rice and coworkers showing that the pyrolysis of many organic compounds at 800–1000 °C removed metallic mirrors, implicating the formation of free radicals. The cleavage of larger free radicals into smaller radicals and olefins under these conditions was also proposed, (10), as well as chain reactions in which radicals abstract hydrogen from alkanes.^{57,58} Reactions of alkyl halides with metal atoms in the gas phase were also found by M. Polanyi and coworkers to yield alkyl radicals (11).^{59,60}

Figure 1 Paneth apparatus. [Reproduced from Ref. 13. © Wiley-VCH Verlag GmbH & Co. KGaA, 1929.]

3.2 Steric Effects and Persistent Radicals

In his early work, Gomberg^{11,12} recognized that steric factors make a contribution to the stability of the triphenylmethyl radical, and Conant and Bigelow⁶¹ in 1928 demonstrated the ability of bulky groups to promote radical formation in the reversible dissociation at 50 °C of 1,2-(di-*tert*-butyl)tetraphenylethane (**26**) to the yellow colored radical **27**, which reacts rapidly with O₂. The radical **27** generated in the presence of Ph₃C[•] forms the mixed dimer **28**.⁶¹ As found almost 50 years later, the di-*tert*-butylbenzyl radical **29** is stable for several days in solution at room temperature, and the EPR spectrum indicates that the phenyl group is twisted into coplanarity with the singly occupied p orbital preventing spin delocalization.^{62,63} Even purely aliphatic radicals without β-hydrogens such as di-*tert*-methyl (**30**) and tri-*tert*-butylmethyl (**31**),⁶⁴ and also even triisopropylmethyl (**32**),⁶⁵ are sufficiently long-lived in solution for direct observation by EPR. These radicals also did not dimerize but decayed by other undetermined routes. Such radicals with kinetic stability have been classified as *persistent radicals*.⁶⁶

The importance of resonance stabilization of triarylmethyl radicals was summarized by Pauling and Wheland in 1933.⁶⁷ Earlier studies by Marvel and Munro had already shown that alkynyl groups with minimal steric barriers were also effective at promoting dissociation of the ethane **33** by stabilization of diarylmethyl radicals **34** (12).⁶⁸

3.3 Diradicals in Aliphatic Rearrangements

Tanatar discovered in 1896 the cyclopropane-to-propene rearrangement, (13),⁶⁹ which was later recognized as proceeding by the formation of a diradical followed by radical rearrangement in an aliphatic system. Chambers and Kistiakowsky⁷⁰ in 1934 measured the kinetics of this reaction, and suggested the radical pathway, (13), that is now generally accepted.

Another diradical species, trimethylenemethane (**35**), was discovered by Dowd in 1966⁷¹ from the cleavage of the pyrazoline, and was characterized by its ESR spectrum and kinetic measurements of its closure to methylenecyclopropane⁷² (14).

The thermal rearrangement of vinylcyclopropanes to cyclopentenes via a diradical intermediate **36**, (15), discovered independently by several groups, was the first reaction widely accepted as proceeding through a diradical intermediate,^{73–78} as supported by computational studies.⁷⁸ This reaction is a synthetically useful method for the preparation of cyclopentenes,⁷⁹ as in the synthesis of **37** (16).⁸⁰

The degenerate cyclization of *Z*-hex-3-en-1,5-diyne, (17), known as the *Bergman rearrangement*, forms the diradical intermediate **38**, and was discovered in 1972, but was initially of largely mechanistic interest.^{81,82} Then it was discovered that this reaction occurs in the action of anticancer drugs, as with the antitumor agents calicheamicin and neocarzinostatin.^{83,84} Many further examples of this process have been studied, including enyne-allene cyclizations.⁸⁴

Enyne-ketene rearrangement is a useful but somewhat unappreciated route to free radicals, discovered with the investigation of the intramolecular cycloaddition of Enyne-ketenes and of aryldienylketenes giving rise to diradical intermediates. For example, **39** in refluxing *p*-xylene gives Enyne-ketene formation followed by competitive *p*-benzoquinone and cyclopentene-3,5-dione formation, in a process interpreted as involving the formation of diradical intermediates which lead to the observed products by hydrogen migration (18).⁸⁵ The competition between the two routes has been studied by computational methods, and is explained⁸⁶ as reflecting the ability of the phenyl substituent to stabilize the radical intermediate, favoring formation of the

five-membered ring, versus the gain in aromatic stabilization in formation of the six-membered ring product. The selectivity between the formation of two reactive diradical intermediates depending upon the substitution pattern allows the design of precursors in which the diradical intermediate can react intramolecularly favoring one product or the other, and has found wide application in synthesis.

3.4 Rearrangements of Monoradicals

Radical rearrangements⁸⁷ were observed in 1951, Roberts and Mazur^{87,88} in the free-radical chlorination of methylcyclopropane gives a mixture of cyclopropylmethyl chloride and 4-chloro-1-butene (19). This reaction was studied further,⁸⁹ and in 1969 Kochi, Krusic, and Eaton⁹⁰ observed the cyclopropylcarbinyl radical **41** by EPR and also monitored the kinetics of this rearrangement.

Radical addition to a diallylammonium species forming radicals **42** leading to six-membered rings

was discovered in 1957 as occurring during polymerizations (20).⁹¹ This cyclization/polymerization also occurs upon formation of radicals by additions to 1,6-heptadienes.⁹²

Other radical cyclizations have been subsequently reported,^{93,94} and cyclization of the hexenyl radical **43** forming the cyclopentylmethyl radical, (21), has been of significant utility in both synthetic and mechanistic study.^{95–97} The competition between formation of cyclopentylcarbinyl and cyclohexyl radicals often favors the former even though the latter is more stable, and this kinetic preference is explained by the more favorable geometry for bond formation from the radical site to C2 of the alkene. The effects of substituents on the double-bond, heteroatoms in the chain, and many other factors on the partitioning between these two paths have been examined.

Ring-expansion reactions of free radicals are also useful in synthesis, (22), and examples were reported independently in 1987 by the groups of Beckwith *et al.*^{98,99} and Dowd and Choi.¹⁰⁰

The radical rearrangement of acyloxy groups, (23), was also discovered independently by different groups (see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**),^{101,102} and is known as the *Surzur–Tanner rearrangement*.¹⁰³ It was initially considered to involve a concerted [3,2] acyl

migration process of radical **44** through transition state **A**, but cleavage to a radical cation/anion pair **B** and a concerted 1,2-migration through transition state **C** have also been considered. Calculations support the originally proposed concerted [3,2] acyl shift.¹⁰⁴

The chemistry of radical sites adjacent to phosphoxy centers elicited interest because of the involvement of such species in DNA degradation processes.¹⁰⁵ These species can give rise to rearrangement, elimination, and substitution products, and for some time concerted eliminations and migrations as well as heterolysis to a radical cation and a phosphate anion were considered to be involved (24). Experimental studies of the 1,2-dibenzyl-2-(diphenylphosphoxy)-2-phenylethyl radical and complementary theoretical studies of 1,1-dimethyl-2-(dimethylphosphoxy)ethyl radical have been interpreted as indicating that a radical cation/anion pathway with initial formation of **45** is favored.¹⁰⁵

4 OTHER DELOCALIZED RADICALS

4.1 Monoradicals

Following the discovery of the triphenylmethyl radical, other types of persistent radicals and novel precursors have been investigated, including the tetraphenylallyl radical (**46**)¹⁰⁶ and the pentaphenylcyclopentadienyl radical **47**,¹⁰⁷ both reported by

Ziegler and coworkers. Pentaphenylethane (**48**) was also found to undergo reversible dissociation to free radicals at 100 °C.¹⁰⁸ A reported preparation of the pentaphenylethyl radical has not been reproduced, and this structure and its possible equilibration are evidently unproven.^{109–111}

The phenalenyl radical (**49**) was first reported in 1957.¹¹² This planarized molecule has been extensively examined for possible electronic applications, and its derivatives form stacked “pancake” structures stabilized by pi bonding.¹¹³

The long-lived acyl radical **50** was prepared by Löwenbein and Folberth;¹¹⁴ it reversibly forms a dimer, and reacts only slowly with oxygen to give a peroxide. Radical **50** and its analogs¹¹⁵ have found extensive recent application as chain-breaking antioxidants.^{116,117} These function by trapping

peroxyl radicals, and can completely suppress autoxidation. Diarylacetate radicals **51** also form readily, but undergo reversible formation of dimers, often with para coupling,^{118,119} and reaction with oxygen to form peroxides.^{120,121}

However, even in 1931 the idea of stable radicals met resistance, as Koelsch prepared and submitted for publication a report of the long-lived radical **52**, but the complete unreactivity of the radical toward oxygen seemed improbable, and the manuscript was rejected. In 1957, ESR spectroscopy of the same sample confirmed the identification, and the original manuscript was resubmitted and published.¹²² Further homologs such as **53** and **54** have been reported, and these are found to have singlet and triplet ground states, respectively.^{123,124}

4.2 Di- and Polyradicals

The synthesis of non-Kekulé bi- and polyradicals, which are aromatic compounds for which no Kekulé structures are possible so that double bonds cannot be drawn to two or more of the carbons, has long been of interest. Such extensions of the triphenylmethyl radical motif of Gomberg include the stable diradical **55**, reported by Schlenk in 1915 (Schlenk diradical),¹²⁵ and the analogous 1,3,5-trisubstituted **56**, prepared by Leo in 1937.¹²⁶ These materials have potential application as molecular magnets,¹²⁷ and the study of “high-spin” molecules has continued (see **Physical Properties of Thiazyl Radicals Toward Conductive and Magnetic Materials**).^{128–133}

The tetra-radical **57** was prepared by oxidation of the corresponding tetra-anion with molecular iodine, and identified by the characteristic quintet EPR spectrum.¹³² The zero-field parameter (D/hc) was interpreted as showing threefold symmetry for **57**.¹³² Analogous hepta-radical **58** and deca-radicals have also been prepared.¹³³

More recently, *m*-xylene (**59**), the parent of the Schlenk diradical **55**, was observed upon photolysis of *m*-xylene in an Ar matrix at 10 K,¹³⁴ and the parent **60** of the Leo triradical **56** was prepared both by flash vacuum pyrolysis of the triiodide with

deposition in Ar at 10 K and by photolysis in Ar at 5 K, and was characterized by IR, UV-vis, and ESR spectroscopy.¹³⁵

Non-Kekulé quinodimethanes are biradicaloids of a six-membered ring with methylene substituents, while non-Kekulé polynuclear aromatics are composed of several fused six-membered rings. The synthesis of triangulene (**61**), the simplest and still unknown non-Kekulé polynuclear aromatic, was first attempted by Clar in 1953,¹³⁶ while a trioxo-triangulene trianion **62** was observed by ESR in 1993,¹³⁷ and the synthesis and ESR detection of a sterically protected triangulene **63** was accomplished in 2001.¹³⁸

Tetramethylenebenzene **64**, a conjugated hydrocarbon in violation of Hund's rule, has been generated as an observable long-lived ground state singlet, as identified by the UV spectrum, and confirmed by extensive calculations.^{139–142} A short-lived triplet species also observed by ESR¹³⁹ in these studies is evidently not the triplet of **64**.^{140–142}

The oxyallyl diradical **65** has been shown by experimental and computational studies to be a singlet with a strong carbonyl π bond that closes without a barrier to cyclopropanone.¹⁴³ The hydrocarbon analog trimethylenemethane (**35**), described above, (14), was first observed in 1966, and underwent ring closure to methylenecyclopropane.⁷²

Tetraphenyl-*para*-xylylene **66** was prepared by Thiele and Balhorn in 1904 as an isolable species,¹⁴⁴ and has been characterized by X-ray.¹⁴⁵ This species however has some diradical character, and continues to attract attention after more than 100 years.

The Chichibabin hydrocarbon (**67**)¹⁴⁶ is a further example of an extended linear polyaromatic with diradical character, and is related to the Thiele's

radical **66**. It is unusual for a neutral, even-electron molecule with a closed-shell electronic structure such as **67** to display magnetic activity, and this species has been compared to extended viologens **68**.^{147,148} These yield ambiguous results for their electronic structure using EPR techniques, but **68** was found to have a singlet ground state as determined using Raman spectroscopy.¹⁴⁷ Earlier X-ray studies also favored a singlet structure for **67**, but with significant diradical character.¹⁴⁵ Other related diradicals include **69**,¹⁴⁹ **70**,¹⁵⁰ and the Muller hydrocarbon **71**.¹⁵¹

5 BIS(TRIPHENYLMETHYL) PEROXIDE AND FREE-RADICAL REARRANGEMENTS

Substrates containing the triphenylmethyl group played a decisive role in the discovery and elucidation of free-radical rearrangements (see **Radical Arylations**). In the first reported example, Wieland observed in 1911 that the Gomberg peroxide **3** rearranged upon heating to the pinacol ether **75** in a process attributed to initial dissociation forming an intermediate alkoxyl radical **72**, followed by rearrangement forming the radical **74** which dimerized to give **75** (25).¹⁵² Recent studies have shown this reaction occurs through a phenyl-bridged intermediate **73** (Figure 2), and this undergoes ring-opening giving radical **74**.¹⁵³ Further examples of such *O*-neophyl rearrangements have been reported.¹⁵⁴

Figure 2 Intermediate phenyl-bridged radical from rearrangement of the trityloxyl radical **73**. [Reproduced from Ref. 153. © Wiley-VCH Verlag GmbH & Co. KGaA, 2010.]

In 1944 Urry and Kharasch reported the neophyl rearrangement, (26) in which neophyl bromide upon reaction with magnesium forms the radical **76**, which undergoes the analogous rearrangement of phenyl to carbon forming a stabilized radical which gives the rearranged Grignard reagent.¹⁵⁵ Subsequently, numerous such free-radical rearrangements of the neophyl type, (26), have appeared, and have been reviewed.¹⁵⁶ The McBay rearrangement discovered in 1974 involves phenyl migration with conversion of an enolic radical **77** to an acyl radical **78**, and this undergoes decarbonylation, forming the benzyl radical (27).^{157,158}

Other free-radical rearrangements are noted elsewhere (see **Radical Cation/Anion and Neutral Radicals: A Comparison**), including cyclopropane cleavage, ring-openings of cyclopropylcarbinyl radicals, cyclizations of alkenyl radicals, ring expansions, and rearrangements involving halogen and sulfur atoms.

6 HETEROATOM-CENTERED RADICALS

6.1 Nitrogen-Centered Radicals

The reversible dissociation of colorless tetraphenylhydrazine into the green diphenylaminyl radical at 100 °C was discovered by Wieland in 1911 (28), thus extending the free-radical concept to nitrogen.^{159–161} The rate of this reaction was measured in 1940 by trapping these radicals by nitric oxide, forming diphenylnitrosoamine.¹⁶²

6.2 Nitroxyl Radicals

Arylaminoxyls $\text{Ar}_2\text{NO}^\bullet$ were first reported by Wieland *et al.* in 1914^{163–165} using the tetravalent representation $\text{Ph}_2\text{N}=\text{O}$, and the radical electronic structure as represented by **79** was proposed by Banfield and Kenyon in 1926.¹⁶⁶ These species resemble nitric oxide (NO), and they may be represented as either a nitrogen- or oxygen-centered radical, as can aminoxyl, H_2NO (**80**). Aminoxyls substituted with aliphatic groups bearing alpha hydrogens are subject to disproportionation and are often not isolable. The preparation of the stable nitroxyl radical, 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO, **81**) was reported by Lebedev and coworkers in 1959,^{167,168} followed shortly thereafter in 1961 by the preparation of di-*tert*-butylnitroxyl **82**,¹⁶⁹ and aliphatic aminoxyls have found wide application ever since (see **Nitroxides in Synthetic Radical Chemistry**). Important physiological roles of NO were found later; and NO was named as “Molecule of the Year” in 1992,¹⁷⁰ and studies of this molecule were recognized by the award of the 1998 Nobel Prize in Medicine.

Because nitroxyl radicals do not react with most organic functional groups but combine with free radicals, they have found wide application as radical traps, and in “living” free radical polymerizations (see **Nitroxides in Synthetic Radical Chemistry** and **Fundamentals of Controlled/Living Radical Polymerization**).¹⁷¹ Nitroxyl radicals are also used as spin labels (see **Spin Labels and Spin Probes**), and are formed in spin trapping by nitroso compounds and nitrones (see below).

6.3 Oxygen-Centered Radicals

As noted in Section 2.1, Downes and Blunt in 1879 reported⁶ that hydrogen peroxide in solution was destroyed by sunlight to form two OH radicals, (29), and proposed that these were responsible for the high reactivity of the peroxide (see

Photo Induced Radical Reactions). Later studies of hydrogen peroxide photolysis after almost 50 years gave spectral evidence for the presence of hydroxyl radicals,^{172–174} and addition of hydroxyl radicals to alkenes forming 1,2-diols was reported, (30),¹⁷⁵ but these reactions are not of preparative value.¹⁷⁶ The hydroxyl radical was detected in the interstellar medium in 1963,¹⁷⁷ and this has been a subject of continued study.¹⁷⁸ As described above, dissociation of triphenylmethyl peroxide forming the highly reactive triphenylmethoxyl radical **72** was discovered by Wieland in 1911 (25).¹⁵² *tert*-Butoxy radicals as well as other alkoxy radicals are available from a variety of precursors, including peroxides, peresters, and hypochlorites, and display high reactivity in hydrogen abstraction, as discussed below (see **Overview of Radical Initiation**).

6.3.1 Aryloxy Radicals

Oxidation of phenols produces aryloxy radicals, and these undergo dimerization with C–O bond formation at the ortho or para positions. The dihydroxynaphthol **83** upon ferricyanide oxidation gave an aryloxy radical which reacted by intramolecular cyclization,¹⁷⁹ and the radical **84** was later observed by ESR.^{180,181} The stable dark blue radical 2,4,6-tri-*tert*-butylphenoxyl **85** is formed as a solid by oxidation of the phenol with potassium ferricyanide.¹⁸² Other examples of phenol oxidation with aryloxy formation^{183–185} include the isolation of solid dimers, which have been shown to involve C–O bonding.

6.3.2 Fenton Reaction and Iron-Based Oxidations

The use of H_2O_2 and $\text{Fe}(\text{II})$ for oxidation was reported by Fenton in 1894,¹⁸⁶ and this reaction was proposed to involve hydroxyl radicals by Haber and Weiss (31).¹⁸⁷ This reaction was later developed by Waters¹⁸⁸ and then by Walling¹⁸⁹ for the oxidation of organic compounds by hydroxyl radicals. The details of the process have occasioned considerable debate.¹⁹⁰

In 1983, Barton and coworkers reported the use of iron-based reagents in the functionalization of alkanes (32).^{191,192} The elucidation of the mechanisms has been contentious, but the role of free-radical reactions appears to be well established.^{193,194}

6.3.3 Peroxides and Peroxyl Radicals

The conversion of benzaldehyde in the presence of air to benzoic acid was reported in 1832 by Wöhler and Liebig,¹⁹⁵ and in 1900 Baeyer and Villiger proposed perbenzoic acid (**86**) as an intermediate in the reaction.¹⁹⁶ The currently accepted free-radical chain mechanism for the process was proposed by Bäckström in 1934, involving an intermediate peroxy radical (33).¹⁹⁷ Bates and Spence already in 1931 had considered that photolysis of CH_3I forming $\text{CH}_3^\bullet$ in the presence of O_2 led to peroxy radicals $\text{CH}_3\text{OO}^\bullet$.¹⁹⁸

(33)

Gomberg's discovery in 1900 of the reaction of the triphenylmethyl radical with oxygen to form the peroxide was a strong piece of evidence for peroxy radical formation, (3), and the affinity of radicals for oxygen remains one of their defining characteristics. Haber and Willstätter in 1931¹⁹⁹ proposed a general role for free radicals in oxygen reactions which provided further recognition for such chemical processes.

The known reaction product of the oxidation of cyclohexene was assigned as the hydroperoxide **87** by Criegee in 1936.²⁰⁰ The oxidation of cumene to the hydroperoxide **88** proceeds by a chain mechanism, (34), and the conversion of the hydroperoxide by acid to phenol and acetone in what became a commercially important process was reported by Hock and Lang in 1944.²⁰¹

The oxidation of hydrocarbons (Scheme 1) is of continued interest.^{202,203} Initially formed alkyl radicals react with oxygen giving intermediate peroxy radicals, which undergo self-reaction to form transient tetraoxide intermediates **89**, as was shown by the direct observation of these intermediates at low

Scheme 1 Oxidation of hydrocarbons.

temperatures, and this was confirmed by the occurrence of isotope-scrambling when $^{16}\text{O}_2$ and $^{18}\text{O}_2$ were used in autoxidation with the formation of $^{16}\text{O}^{18}\text{O}$.^{204,205} Tetraoxides with secondary hydrogens (**90**) can undergo disproportionation with formation of singlet oxygen, which can be trapped with added 9,10-diphenylanthracene (Scheme 1).^{204,205}

The biological antioxidant α -tocopherol (vitamin E) serves as a chain-breaking trap of peroxy radicals in hydrocarbon oxidation by hydrogen donation, and the resulting phenoxyl radical then eventually reacts with and destroys a second peroxy radical.^{206,207}

6.3.4 Diacyl Peroxides and Peroxy Esters

The thermal reactions of diacyl peroxides (**91**) were initially studied by Hermans, *et al.*^{208,209} and by Wieland,²¹⁰ but only gradually were these recognized as forming free radicals. The interpretation of the results was complicated by the phenomenon of induced decomposition, also discussed in Section 9.4, in which radicals are formed during the peroxide decomposition or from subsequent radical reactions with solvents, and these then reacted with the radical initiator. Thus, Wieland and Razuvaev²¹⁰ considered radical formation in these reactions but excluded this possibility. Walker and Wild²¹¹ studied the decomposition of acetyl peroxide by both thermal and photochemical means, and observed the formation of methane and ethane, and made a tentative suggestion that these could result from formation of acetoxo radicals $\text{CH}_3\text{CO}_2^\cdot$ which underwent decarboxylation to methyl radicals $\text{CH}_3^\cdot$, and these could combine to form ethane or react with solvent to form methane. The kinetics of benzoyl peroxide decomposition reactions were studied by D. J. Brown,²¹² and was suggested to involve the formation of benzoyloxy radicals, (35), which could form phenyl radicals by decarboxylation. Polar effects in rates of these reactions were found by Swain *et al.*,²¹³ who found a linear correlation of the rates with the Hammett σ values, with

$\rho = -0.38$. This was interpreted as resulting from the enhancement of the reactivity by electron donor substituents because of increased repulsion between the oxygens in the peroxy group in **91**.

Ethyl peracetate was the first ester of a peroxy acid, as characterized by Baeyer and Villiger in 1901.²¹⁴ Kinetic studies of perester decomposition were reported by Blomquist and Ferris in 1951,²¹⁵ and in 1958 Bartlett and Hiatt²¹⁶ proposed that concerted multiple bond scission of peresters **92** could occur when stabilized radicals were formed, and that polar effects in peroxyester decomposition are also significant (36).

6.4 Halogen Radicals

In addition to proposing the dissociation of hydrogen peroxide to hydroxyl radicals, as noted in Section 2.1, Downes and Blunt in 1879 also suggested⁶ that chlorine molecules were dissociated by light to form two Cl radicals, and that these were responsible for the high reactivity of chlorine. The study of the kinetics of gas phase reactions of halogen free radicals was reported by Bodenstein and Lind in 1906,²¹⁷ as later summarized,²¹⁸ and it was found that reactions of H_2 with Cl_2 and Br_2 were complex processes. A radical chain mechanism for these reactions was proposed in 1919 by Christiansen, Herzfeld, and Polanyi (Scheme 2) (see **Halogen and Chalcogen Transfer Chemistry**).^{219–221} As described above, the theoretical basis for understanding these reaction in terms of free radicals was presented by G. N. Lewis in 1916, with the theory of the electron-pair bond, and free radicals, or “odd molecules.”^{52,53} Further

Scheme 2 Reactions of dihalides with H_2 under radical conditions.

Scheme 3 Reduction of PbCl_2 with H radicals.

studies on chain reactions including the extension to explosions in gaseous systems were made by Hinshelwood and by Semenov,^{222–224} who shared the Nobel Prize in 1956.

In 1924, Bonhoeffer demonstrated the formation of atomic hydrogen using an electric discharge (Scheme 3). The presence of atomic hydrogen was shown by its ability to reduce metal salts.⁵⁶

6.4.1 Free-Radical Additions

Michael Faraday reported in 1821 that chlorine addition to tetrachloroethylene forming hexachloroethane is stimulated by sunlight,²²⁵ indicating the involvement of a free-radical process. Later studies of this reaction showed inhibition of halogen addition by reaction of the intermediate radicals with oxygen,^{226–228} and a free-radical chain mechanism was proposed (37). Similar chain mechanisms were proposed in 1927 by Berthoud and Béraneck²²⁹ for the isomerization of stilbene catalyzed by Br_2 , (38), by Wachholtz²³⁰ for bromine addition to ethyl maleate, (39), and by Bauer and Daniels for cinnamic acid.²³¹ Further kinetic and mechanistic studies were reported for free-radical addition of Br_2 to phenanthrene,²³² and for the reaction of Cl_2 with benzene.²³³

6.4.2 The Peroxide Effect

The addition of HBr to allyl bromide in the presence of light and air occurs rapidly to yield 1,3-dibromopropane, whereas Kharasch and Mayo in 1933²³⁴ demonstrated that, in the absence of air and with purified reagents, the reaction is slow and 1,2-dibromopropane is formed. The latter reaction is the normal addition occurring by an ionic pathway giving the Markovnikov orientation. In 1933, the mechanism of the abnormal process (“anti-Markovnikov” addition) was not discussed, and it was only in 1937 that the free-radical chain mechanism was proposed by Kharasch and his coworkers for this process.^{235,236} The mechanism was extended to the reaction of propene with HBr, for which the role of peroxides in promoting the reaction was demonstrated in (40) and (41). The same mechanism was independently proposed in 1937 by Hey and Waters.²³⁷ This process is taught in most beginning organic chemistry courses, and has bedeviled many generations of students.

Interestingly, in 1934 Rice and Rice had incorrectly proposed⁵⁸ a free-radical chain mechanism for

the normal Markovnikov addition. They suggested that the anti-Markovnikov product arose from a different process, which was yet to be elucidated. In retrospect and with the benefit of hindsight, it is surprising that Kharasch was slow to recognize the peroxide effect as resulting from free-radical reactions, given the large body of precedent from other studies, particularly from his contemporaries Taylor and Rice. However, Kharasch approached these studies from a completely different perspective, and his work originated from a desire to develop a theory for polar reactions.²³⁸ Once he recognized the role of free radicals, he devoted the rest of his career to their study, and developed many of the modern concepts of these intermediates.

At the same time, Robert Robinson with Urushibara was studying the addition of HBr to fatty acids, and noticed that the direction of addition was reversed upon exposure to moist air, as first reported in 1933.^{239,240} Initially, these authors supposed that the moisture possibly caused the effect.²⁴⁰ Urushibara became Professor at Tokyo, and continued studies of the peroxide effect, and was the founder of organic free-radical studies in Japan.

6.4.3 Free-Radical Halogenations

The halogenation reactions of alkanes found early applications, particularly in industrial processes, and in 1930 the kinetics of the gas-phase photochlorination of chloroform to carbon tetrachloride was reported by Schwab and Heyde, (42),²⁴¹ while the kinetics of the chlorination of methane was described by Pease and Walz in 1931.²⁴² Both these studies showed the currently accepted mechanism, which was extended to reactions in solution by Hass *et al.*^{243,244}

The free-radical halogenation mechanism of other alkanes was described by Kharasch and coworkers,^{245–247} and in 1940 Brown, Kharasch, and Chao found that during free-radical chlorination of optically active 2-methyl-1-butyl chloride, the product 1,2-dichloro-2-methylbutane was racemic, implying that the intermediate radical was either

planar or rapidly inverting (43).²⁴⁵ However, radical formation at a bridgehead center, constrained to maintain nonplanarity in bicycloheptyl intermediate **93**, was also demonstrated (44).²⁴⁶

6.4.4 Migration and Bridging in Radicals

Migrations of chlorine, bromine, and thiol groups in free-radical reactions have been observed,^{248,249} and the role of bridging in these species has been a subject of some dispute.²⁵⁰ Reaction of a chiral substrate involving the bridged radical **94** gives an optically active product, (45), in direct contrast with chlorination in which racemization occurred in (43).

6.4.5 N-Bromosuccinimide

Wohl in 1919 reported that *N*-bromoacetamide (CH_3CONHBr)-induced allylic bromination.²⁵¹ Then, *N*-bromosuccinimide (**95**) was described in 1942 by Ziegler and coworkers to be useful in such free-radical bromination reactions, (46),²⁵² and the resulting widely utilized procedure is known as the *Wohl–Ziegler reaction*. In 1963, the mechanism of the reaction was proposed to involve halogen atoms in the hydrogen abstraction step,^{253,254} instead of succinimidyl radicals as had been commonly supposed.

6.5 Sulfur-, Silicon-, and Tin-Centered Radicals

The effect of air and the acceleration by light of the addition of PhSH to styrene was observed in 1928,²⁵⁵ and in 1934 the formation of the PhS• radical from dissociation of PhSSPh and from reactions of PhSH was proposed.^{256,257} The use of peroxides to catalyze the reaction was reported by Jones and Reid in 1938,²⁵⁸ and in the same year the radical chain mechanism for this process was proposed (47) and (48).²⁵⁹

The formation of silyl radicals was reported in different laboratories in 1947 by Sommer and Whitmore, who discovered silane additions to alkenes (49) and (50),²⁶⁰ and by Barry *et al.* at Dow Chemicals.²⁶¹ These have been utilized extensively in both mechanistic and synthetic studies, including halide reductions (see **Silanes as Reducing Reagents in Radical Chemistry**).^{262,263}

Tin radicals were first reported by Noltes *et al.* in 1956,²⁶⁴ and their applications in organic chemistry were pioneered by Kuivila and coworkers.^{265,266} These species have proven to be of great utility in synthesis (see **Tin Hydrides and Functional Group Transformations**), particularly in reductions

of organohalogen compounds, although their toxicity and other unfavorable properties have led to a search for substitutes.²⁶⁷ Interestingly, in the initial publication of addition of triphenyltin hydride to styrene, (51),²⁶⁴ it was proposed that the reaction did not involve a free-radical mechanism, as no inhibition by hydroquinone was detected.

7 ELECTRON TRANSFER PROCESSES

7.1 Carbonyl Reduction

The reaction of sodium metal with benzophenone in ether gives rise to a blue color, as first observed by Beckmann and Paul in 1891.²⁶⁸ From the fact that reaction of this species with iodine or oxygen re-forms benzophenone, Schlenk and Weickel proposed in 1911 that this species was the ketyl radical **96** (52).²⁶⁹ Further experiments showed this was in equilibrium with the dimer **97**, which gives benzpinacol upon hydrolysis.²⁷⁰ Magnetic susceptibility measurements suggested that **96** was largely associated to the dimer,^{270,271} while the potassium derivative was largely dissociated.²⁷¹ Later, these radicals were investigated by ESR, and finally the structure of **96** was determined by X-ray crystallography.²⁷² In 1934, Favorsky and Nazarov proposed the formation of a ketyl radical anion from the aliphatic ketone *t*-Bu₂C=O,²⁷³ and the ESR spectrum of this radical was first observed in 1961.²⁷⁴ Studies of reduction of ketones by metals were extended to α,β -unsaturated ketones in 1926 by Conant and Cutter.²⁷⁵

7.2 Birch Reduction

Birch in 1944²⁷⁶ extended the findings of Wooster and Godfrey,²⁷⁷ and demonstrated that Na metal

in ammonia reduces benzene, anisole, and other aromatics to 1,4-cyclohexadienes. This transformation is known as the *Birch reduction*, and has been extensively utilized in synthesis.²⁷⁸ Birch speculated about the mechanism of this reaction, but did not explicitly describe a radical pathway involving **98**, (53) until later, as described in his autobiography.²⁷⁹

Kim and Bunnett in 1970 made the unexpected observations of reactions occurring by an electron transfer chain mechanism in aromatic systems (55).^{283,284} The selective formation of **108** from **105** showed that benzyne intermediates were not formed, and a chain reaction mechanism analogous to that found in the aliphatic systems above, (54),^{283–285} was proposed.

7.3 Electron Transfer in Substitution Reactions

Reactions occurring by an electron transfer chain reaction in aliphatic systems were reported independently in 1966 by the groups of Russell and Danen²⁸⁰ and Kornblum *et al.*^{281,282} Reaction of enolate **99** with 4-nitrobenzyl chloride (**100**) involves initial transfer of an electron to **100**, forming radical **101** together with radical anion **102** which loses chloride forming a benzylic radical which combines with **99** forming the radical anion **103** which transfers an electron to **100**, giving the product **104**, as well as another radical anion **102**, which continues the chain process (54).

7.4 Radical Cations

Wurster and Sendtner already in 1879 had prepared crystalline salts containing radical cation **109**, (56).²⁸⁶ Subsequently, radical cations of many different structural types were prepared,^{287,288} including a cyclophane structure **110** containing two radical cations.²⁸⁹

Leonor Michaelis made extensive studies of oxidations in biological systems,^{290–293} and reported in 1931 the formation of the radical cation species **111**, which he designated as a semiquinone.^{290,291} Michaelis also studied the oxidation of quinone anions, and demonstrated the formation of semiquinone radical anions such as **112** (57).^{292,293} Quantitative linear free energy correlations of oxidation potentials with the rates of formation of these species were found by Dimroth.²⁹⁴

Oxidative electron transfer from a polycyclic aromatic compound was found by Weiss in 1941, who obtained crystalline salts of $C_{14}H_{10}^+$ from oxidation of anthracene, as well as salts from coronene, 1,2-benzperylene, and 3,4-benzpyrene (see **Redox Properties of Radicals**).²⁹⁵

8 NEW CLASSES OF TRIARYLMETHYL RADICALS

8.1 Perchlorinated Triarylmethyl Radicals

Perchlorination of aromatic compounds using a reagent composed of sulfur monochloride and aluminum chloride in sulfuryl chloride (SCM reagent), introduced in 1960,²⁹⁶ has proved very effective in the preparation of a new class of stable triarylmethyls. In 1971, this method was applied to the formation of perchlorinated diphenyl- and triphenylmethane, and conversion of the former to the radical perchlorodiphenylmethyl (**113**) could be effected by reduction with $FeCl_2$, (58) and, more generally, the radical perchlorotriphenylmethyl (**114**) was prepared by conversion of the chlorocarbon to the anion with NaOH in dimethylsulfoxide (DMSO), and oxidation of the corresponding anion with iodine (59).^{297,298} These radicals have lifetimes in air of decades, and are characterized as inert carbon free radicals.^{297,298} The *ortho*-chlorines on the aryl rings effectively shield the central radical site, preventing reactions of the chlorinated radicals.

These studies have been extended to perchlorinated diradical **115**, and to the corresponding radical cations and radical anions, which have single-electron transfer equilibria,²⁹⁸ and to the highly but not completely perchlorinated diradical **116**.²⁹⁹

susceptible to electron transfer, either reduction to carbanions or oxidation to carbocations (see **Redox Properties of Radicals**).²⁹⁸

There is essentially no delocalization of the free electron into the twisted perchlorophenyl rings, but, because of the steric shielding, normal atom transfer reactions or radical combination reactions are strongly inhibited. While these radicals are remarkably inert to almost all reagents, they are

Perchlorinated triarylmethyl radical **117** combining perchlorotriphenylmethyl and bis(4-methoxyphenyl)amine moieties was used to study electron transfer and charge transfer properties. The absorption spectrum of this highly soluble compound was studied in 13 solvents.

The electronic coupling and the dipole moments of the ground and excited states were also determined.^{299,300}

The dependence of the UV spectra of the transition from radical **118** to the zwitterion **119** was examined as the solvent composition was varied and the process changed from the normal to the inverted Marcus region (60).³⁰¹

which was captured as the peroxide.³⁰⁴ Similarly, 4-fluorophenyl(diphenyl)methyl chloride lost fluorine on treatment with silver, indicating the formation of an analogous radical,³⁰⁵ but halogens in the 3-position are inert under these conditions.³⁰⁶

Perfluorinated triphenylmethyl radical **120** was generated by the reduction of the corresponding carbocation, and gave an EPR spectrum measured in benzene (61).^{302,303}

Earlier studies of less substituted (4-halophenyl)diarylmethyl radicals indicated that these underwent dehalogenation upon the formation of unsymmetrical dimers. For example, reaction of 4-bromophenyl(diphenyl)methyl chloride with silver evidently proceeds with the formation of radical **121**, which after dimerization lost the allylic bromine forming **122** (62),

8.2 Tetrathiatriarylmethyl (TAM) or Trityl Triarylmethyl Radicals

A recent development in the study of triarylmethyl radicals has been with tetrathiatriarylmethyl (TAM) trityl radicals which are finding extensive and increasing use in imaging applications using EPR spectroscopy because of their extraordinary stability in cells and tissues, narrow line widths resulting in high analytical resolution at concentrations in the micrometer range, and enhanced sensitivity to oxygen.^{307–315} These compounds and various structural variations were originally developed in industry for use as contrast agents in Overhauser magnetic resonance imaging (OMRI), and were first reported in the patent literature.³⁰⁹ Important characteristics of these materials are the narrow signals promoted by the absence of inhomogeneous hyperfine couplings. An earlier preparation of these compounds³¹⁰ has been improved by a convenient large-scale synthesis of **123** and the sodium salt

of **124** (known as *Finland trityl*).³¹¹ The radical **124** was formed in one step in quantitative yield by treatment of the tri(*tert*-butyl ester) **123** in neat trifluoroacetic acid at room temperature (63).³¹¹

These serve as dual-function pH and oxygen probes. Dendritic TAM molecules were prepared in which encapsulation of the radical by the dendrimer enhances their stability and solubility in water over a wide pH range, and the Cu(II) complex of **125** is a highly effective pH probe.³¹⁴

Another of these widely studied radicals is Oxo63 (**126**), which has been extensively derivatized for optimum properties.^{312,315} This reacts with superoxide ($O_2^{\cdot-}$) radicals, (64), and was used for the assay of superoxide by monitoring the newly formed product absorption peak at 546 nm, and gave good agreement with the widely used cytochrome *c* method of superoxide detection.³¹⁵

125

9 RADICAL PROCESSES

9.1 Free-Radical Initiators

9.1.1 Azo Compounds (Diazenes) as Sources of Free Radicals

As described above, phenylazotriphenylmethane, (2), was used by Gomberg^{9,10} in the classic preparation of tetraphenylmethane. Wieland *et al.*, in 1922,⁴⁵ showed that $\text{Ph}_3\text{C}^\bullet$ (1) was formed in this reaction, and proposed phenyl radicals were formed as well (65).

In the 1920s, kinetic studies by Ramsperger^{316–319} on the thermal reactions of azoalkanes demonstrated that substituent effects on both sides of the molecule could affect the ease of decomposition, implying

concerted reaction if suitably stable radicals could be formed, and were interpreted as showing that these reacted in one step to form two alkyl radicals and N_2 (66) (see **Overview of Radical Initiation**). However, later consideration of this reaction suggested that, for azomethane ($\text{R}=\text{CH}_3$), initial one-bond cleavage occurs.³²⁰ In 1933, Leermakers³²¹ used the Paneth mirror technique to demonstrate that methyl radicals were indeed generated upon pyrolysis of azomethane. Studies by two different groups in 1934 established that methyl radicals from azomethane abstract hydrogen from CH_3CHO in a chain reaction forming methane (67),^{322,323} and in 1938 it was found that during azomethane photolysis essentially all of the methyl radicals could be trapped by nitric oxide (68).³²⁴ Extensive further work on substituent effects in diazene reactions has been reviewed, including examination of polar, conjugative, and steric substituent effects.³²⁰

In 1998, Zewail and coworkers re-examined the decomposition of azomethane ($\text{CH}_3\text{N}_2\text{CH}_3$) with laser excitation at 310 nm and found the two C–N bond-breaking reactions to occur in separate steps on the femtosecond timescale, with detection of the intermediate $\text{CH}_3\text{N}_2^\bullet$.³²⁵ For studies of such fast reactions, Zewail was awarded the 1999 Nobel Prize in Chemistry.

Photochemical denitrogenation of the stereolabeled diazabicyclo[2.2.1]heptene **127** leads to a mixture of inverted and retained bicyclo[2.1.0]pentane (housane) products, and the role of solvent viscosity in this reaction has been examined by Adam *et al.* and interpreted in terms of the frictional impediment (viscosity effect) on the bond rotation in the inversion of the diradical intermediate **128**, leading to the product **129** (69).³²⁶

9.2 Free-Radical Formation in Grignard Reactions

The formation of coupling and reduction products in the Grignard reactions of alkyl halides with magnesium led to the suggestion by Gomberg and Bachmann that free radicals are formed in these processes, (70),³²⁷ and this has been generally accepted.³²⁸ However, there has been a long and contentious debate as to the extent that the reactions of these radicals occur while adsorbed on the metal surface as opposed to freely diffusing through the solution and back to the metal surface.³²⁹ The reactions of Grignard reagents with carbonyl compounds have also been found to proceed by

single-electron transfer processes in some examples (71).^{330,331}

9.3 Photochemical Generation of Free Radicals from Ketones

The photolysis of ketones was suggested by Norrish *et al.*^{332,333} to involve the formation of free radicals, and this was confirmed by experiments in which metallic mirrors were removed.^{334,335} In the type I reaction, an initial cleavage of the C–C bond forming an acyl radical was suggested to occur upon photoexcitation, (72), and this can be followed by the loss of carbon monoxide giving a further alkyl or aryl radical (see **Synthetic Radical Photochemistry**). The type II cleavage involves the initial formation of a biradical intermediate **130**, (73), and was directly observed by Zewail and coworkers.³³⁶

The assignment of the excited state of benzophenone as a triplet biradical which could act as a sensitizer was made by Hammond and Moore in 1959, (74),³³⁷ and this led to a great surge in radical study using photochemical techniques. The role of photoexcited benzophenone as a diradical initiator for benzaldehyde oxidation was previously shown explicitly by Bäckström in 1934 (74).¹⁹⁷

9.4 Induced Decomposition of Radical Initiators

The phenomenon of induced decomposition, in which radicals derived from reaction of the solvent (SH) with the initiator benzoyl peroxide consume some of the initiator, was elucidated by Bartlett and Nozaki, (75),^{338,339} and by Cass.³⁴⁰ These results helped in the elucidation of many of the difficulties in interpreting the results of reactions of radical initiators, as noted above.

The direct reaction of free radical initiators with nonradical substrates such as tertiary amines resulting in the formation of free radicals has also been observed.^{341–343} Other examples are the reaction of diacyl peroxides with alkenes, (76),³⁴⁴ and the reaction of hypochlorites with alkenes and alkynes.³⁴⁵

9.5 The Cage Effect

The cage effect, or the enhanced probability for recombination of two radicals formed in close proximity in solution with impediment to separation due to collisions with surrounding solvent molecules, was discussed by Franck and Rabinowitch in 1934,³⁴⁶ and Rabinowitch and Wood³⁴⁷ used a “pinball” illustration of this process (Figure 3). The theory of this reaction was further developed by Noyes.³⁴⁸

The effect of solvent viscosity on cage effects in solution was demonstrated in 1967 by Kiefer and Traylor (77).³⁴⁹ Thus the viscosity of the solvent had a major effect on the yield of di-*tert*-butyl peroxide formed from cage recombination of the *tert*-butoxy radical pair formed from thermolysis of di-*tert*-butyl peroxyoxalate (**131**). The efficiency of cage combination was also affected by the initial separation in the radical pairs formed from different

Figure 3 Apparatus for simulating the cage effect. [J. Franck and E. Rabinowitch, *Trans. Faraday Soc.*, 1934, **30**, 120–130. Reproduced by permission of The Royal Society of Chemistry.]

precursors. The effect of mass on cage recombination has also been shown, using organometallic radicals.³⁵⁰ Generation of radical pairs constrained in zeolites involve “supercages”, as investigated by Turro *et al.*^{351,352}

9.6 Free-Radical Inhibitors: DPPH and Galvinoxyl

The stable free radical diphenylpicrylhydrazyl (**132**) was first prepared by Goldschmidt and Renn in 1922,³⁵³ and this³⁵⁴ and galvinoxyl (**133**)³⁵⁵ have frequently found application as radical scavengers in kinetic studies.³⁵⁶ The triaryl analogs **134** and **135** of **133** have also been generated by oxidation–reduction processes (78).³⁵⁷

9.7 Spin Trapping

The additions of transient radicals to nitroso compounds, (79)^{358,359} and to nitrones, (80),³⁶⁰ were found to form stable nitroxyl radicals, and these may be conveniently detected by ESR for the identification of the transient radicals. This technique has been extensively applied in chemical and biological systems.^{361–367}

The name “spin trapping” was coined by Janzen,³⁶³ and derives from analogy with the use of stable nitroxyls as “spin labels” or “spin probes,” (see **Spin Labels and Spin Probes**), which provide spectroscopic information regarding their microscopic environment, a procedure pioneered by McConnell *et al.*³⁶⁸

9.8 Free-Radical Polymerization

Taylor³⁶⁹ in 1926 demonstrated that hydrogen atoms generated by the mercury-sensitized photodecomposition of hydrogen gas add to ethylene to form ethyl radicals, which were proposed to react with H_2 to give the observed ethane and another hydrogen atom. Evidence that polymerization could occur by free-radical reactions

was found by the observation that ethyl radicals formed by the gas-phase pyrolysis of diethylmercury or tetraethyllead initiated the polymerization of ethylene,³⁷⁰ and this process was extended to the solution phase by Cramer (see **Kinetics of Polymerizations and Basic Concepts on Radical Chain Reactions**).³⁷¹ The mechanism, (81), (with participation by a third body) was presented for the reaction,^{369,370} which is in accord with current views, and a mechanism, (82), was shown for disproportionation. Staudinger in 1932 presented a mechanism for free-radical polymerization of styrene,³⁷² but just as did Rice and Rice in 1935,⁵⁸ showed the radical attack on the most substituted carbon (anti-Markovnikov attack). The correct orientation was shown by Flory in 1937.³⁷³ In 1935, Rice and Sickman reported that ethylene polymerization was also induced by methyl radicals generated from thermolysis of azomethane.³⁷⁴

9.9 Free-Radical Aromatic Substitution

There are a number of processes for free radical substitution in aromatic systems, including the Pschorr

reaction, that involve intramolecular cyclization of an aryl radical with a side chain aryl group (see **Radical Arylations**). This was reported in 1896, although its radical character was not yet recognized (83).³⁷⁵

The formation of phenyl radicals by the thermolysis of diacyl peroxides was proposed by Hey, Waters, and coworkers,^{237,376} and these were proposed to give free-radical aromatic substitution via intermediate **136** (84). This mechanism was also applied to the formation of biaryls from diazonium ions in benzene,³⁷⁷ a conversion now known as the *Gomberg–Bachmann reaction*. Initially, such free radical substitutions on aromatic rings were suggested^{237,376} to involve displacement of hydrogen atoms, but it is currently accepted that these reactions are much more likely to involve intermediates from which hydrogen is abstracted by another radical (84). Kinetic and mechanistic studies of free-radical reactions of halogens with aromatics were also studied, as noted above.^{232,233}

9.10 Remote Radical Functionalization

It was shown by Barton *et al.*³⁷⁸ that the photolysis of steroidal nitrites **137** proceeding by formation of alkoxy radicals could result in hydrogen abstraction from suitably situated methyl groups forming carbon-centered radicals which then reacted with the

nitric oxide generated to give oximes (85) (see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**). This permitted the functionalization of the unactivated centers.

A comparable functionalization of remote centers was achieved by Breslow and Winnik,³⁷⁹ in which photolysis of hydrocarbons with a benzophenone moiety attached by a tether of suitable length (**138**) resulted in abstraction of hydrogen by the excited benzophenone from the hydrocarbon chain. This achieved functionalization of the hydrocarbon chain (86).

9.11 PTOC Esters

Pyridine-2-thione-*N*-oxycarbonyl (PTOC) derivatives of carboxylic esters **139** were developed by

Barton *et al.*, and serve as a convenient source of carboxy radicals, which upon decarboxylation provide specific routes to free radicals (87).^{380,381} This process can also proceed by a chain reaction. Acyl radicals also find many uses, and this has been reviewed.³⁸²

10 CONCLUSION

The history of free radicals in chemistry involved an uncertain beginning, and then two decisive moments arrived, when first triarylmethyl and then unstabilized aliphatic radicals became well-recognized intermediates. Then followed a sustained development of the subject, with some missteps, but free-radical chemistry is thriving today with a seemingly unlimited future. It is noteworthy that the two leading pioneers, Gomberg and Paneth, did not receive the Nobel Prize, while others such as Wieland, Ziegler, and Barton received the Prize for unrelated work, and individuals such as Zewail, Herzberg, Flory, Norrish, and Porter, who built on the original discoveries, were recognized for their later discoveries. It may be expected with confidence that further remarkable discoveries are still to come.

Supramolecular Radical Chemistry

Marco Lucarini

Department of Organic Chemistry "A. Mangini", University of Bologna, Bologna, Italy

1 INTRODUCTION

Supramolecular chemistry refers to the area of chemistry of "multicomponent" molecular assemblies in which the component structural units are typically held together by a variety of weak (non-covalent) interactions.¹ While traditional chemistry focuses on the covalent bond, supramolecular chemistry examines the weaker and reversible non-covalent interactions between molecules. These forces include hydrogen bonding, metal coordination, hydrophobic forces, van der Waals forces, π - π interactions, and electrostatic effects. Important concepts that have been demonstrated by supramolecular chemistry include molecular self-assembly, folding, molecular recognition, host-guest chemistry, mechanically interlocked molecular architectures, and dynamic covalent chemistry.¹

It must be underlined that supramolecular concepts have not aroused too much interest so far in the community of radical chemists. This is a logical consequence of the common idea that the reactivity and spectroscopic properties of free radicals cannot be significantly modified by weak forces such as those involved in supramolecular chemistry. A typical range for supramolecular intermolecular interaction comprises between circa 10 kcal mol^{-1} and much less than kT (circa 1 kcal mol^{-1}). In spite of the small value of these forces, it has been shown that, under specific conditions, they can control the reactivity of a free radical in an unexpected manner.

This article describes both the application of the concepts of supramolecular chemistry to control the

reactivity of organic free radical and how electron paramagnetic resonance (EPR) methods (see **Analysis of Radicals by EPR**) have been extensively used for detecting and identifying noncovalent assemblies in solution and for clarifying their structure and properties. Because of the many topics covered by supramolecular chemistry, this article describes only selected works that appeared in the literature. The readers are invited to consult review papers cited in this work to get a complete picture on each topic.

2 HYDROGEN BONDING

Hydrogen-bonding effects are important in modulating free radical properties. In spite of the tiny value of this force (a typical value for an individual intermolecular hydrogen bond is circa $4\text{--}6 \text{ kcal mol}^{-1}$),² it has been shown that it can control the spectroscopic, thermochemical, and kinetic properties of free radicals in a spectacular manner. In particular, oxygen-centered radicals are known to significantly change their properties on formation of a hydrogen-bonded complex on the oxygen atom retaining the unpaired electron.

The first successful EPR detection in a solution of a hydrogen-bonded radical complex showing hyperfine coupling with the hydrogen-bonded protons has been reported by Fukuzumi *et al.* in 2007 for a semiquinone radical anion deriving from 1-(*p*-tolylsulfanyl)-2,5-benzoquinone (TolSQ) hydrogen bonded with a protonated

Figure 1 (a) EPR spectrum of TolSQ^{•-}/His·2H⁺ recorded in the presence of histidine and HClO₄ in deaerated MeCN at 298 K. (b) Spectrum simulated with the hfsc values of TolSQ^{•-}/His·2H⁺. [Yuasa *et al.* (2007). Ref. 3. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.]

histidine (His·2H⁺).³ The EPR spectrum of such hydrogen-bonded complex (TolSQ^{•-}/His·2H⁺) was detected after photoinduced electron transfer (ET) from 10,10'-dimethyl-9,9'-biacridine to TolSQ in the presence of His·2HClO₄ in acetonitrile at 298 K.⁴ The EPR spectrum is well reproduced by a simulated spectrum with hyperfine splitting constant (hfsc) values of $a_{3H} = 0.88$, 5.31, and 6.08 G and superhyperfine splitting due to one nitrogen atom and three equivalent protons ($a_N = 1.35$ G and $a_{3H} = 2.97$ G) of His·2H⁺ (Figure 1). Hydrogen bonds are found between the C=O oxygen atom of TolSQ^{•-} and the COOH proton as well as the NH₃⁺ protons of His·2H⁺, and also between the S=O oxygen atom of TolSQ^{•-} and the NH⁺ proton of the imidazole ring of His·2H⁺. Complete agreement of the observed EPR spectrum with the simulated spectrum (Figure 1) was considered as a clear indication of the formation of the TolSQ^{•-}/His·2H⁺ complex. Actually, the g value and the hfsc values of TolSQ^{•-}/His·2H⁺ are drastically changed from those of TolSQ^{•-} in the absence of His·2H⁺, which are $g = 2.0057$ and $a_{3H} = 2.00$, 2.20, and 3.35 G.

The strong hydrogen bonding between TolSQ^{•-} and His·2H⁺ is also responsible for the significant increase in the electron acceptor ability of TolSQ. Similar effects of hydrogen bonding on E_{red} of quinones have been previously reported.^{5–8}

Oxidation of phenols is facilitated by the presence of a proton-accepting group such as an amine, forming a hydrogen bond in the corresponding phenoxyl radical: these phenols (Scheme 1), having a pendant hydrogen-bonded base, are characterized by lower redox potentials with respect to other phenols.^{9–14}

Scheme 1 Oxidation of a phenol with a pendant base group.

The product of chemical and quasi-reversible electrochemical oxidations in each case is the phenoxyl radical in which the phenolic proton was transferred to the base, 'OAr-BH⁺, through a proton-coupled electron transfer (PCET) process and is hydrogen bonded to the oxygen atom retaining the unpaired electron.

Phenoxyl radicals are also known to change their thermochemical properties on formation of a hydrogen-bonded complex on the oxygen atom retaining the unpaired electron. In phenols, the O–H bond dissociation enthalpy, which in hydrogen-bond-accepting solvents (HBA) is larger than in hydrocarbons due to the preferential stabilization of the starting phenol with respect to the phenoxyl radical (see **Antioxidants in Chemistry and Biology**), is lowered in the presence of hydrogen-bond-donating (HBD) solvents because they preferentially stabilize the phenoxyl radical (Figure 2). For example, in the presence of strong HBD solvents such as 1,1,1,3,3,3-hexafluoropropan-2-ol (HFP), the preferential stabilization of the phenoxyl radical results in a decrease in the measured BDE(O–H) in the *p*-methoxy phenol of about 1 kcal mol⁻¹.¹⁵

Figure 2 Hydrogen bonded α -tocopheroxyl radical.

Scheme 2 Reaction scheme for the reaction between a model hydroquinone and peroxy radicals in the presence of small amounts of DMSO.

The different strengths of the hydrogen bonds formed in the parent phenol and in the phenoxyl radical are also responsible for the unexpected reactivity increase of a model hydroquinone toward free radicals upon the addition of small amounts of HBA solvents.¹⁶ Actually, it has been observed that the addition of small amounts of DMSO results in a five times increase in the rate constant for the reaction of 2,5-di-*tert*-amylhydroquinone with peroxy radicals for the complexed hydroquinone with respect to the free hydroquinone. This behavior has been explained quantitatively in terms of the different strengths of the hydrogen bonds formed in the parent phenol and in the phenoxyl radical between the solvent and one of the hydroxyl groups (Scheme 2).

Complexation by HFP of phenoxyl radicals has important effects also on their persistency. Actually, the intensity of the EPR spectra is generally higher in the presence of the fluorinated alcohol, this effect

Scheme 3 Reaction scheme describing the kinetic solvent effects for the self-decay of secondary peroxy radicals observed in the presence of a strong hydrogen bond donor.

being particularly evident in the case of the radical derived from α -tocopherol, which is detectable by EPR at room temperature for several hours.¹⁵ Because the decay of α -tocopheroxyl radicals takes place by a bimolecular disproportionation reaction, to occur in the presence of HFP it requires the desolvation of at least one radical molecule with a consequent reduced reactivity. This behavior is similar to that found for the α -tocopheroxyl radical in the presence of magnesium ions by Nakanishi *et al.*¹⁷

Fluorinated alcohols such as HFP have also a significant effect on the persistency of peroxy radicals. Actually, the formation of a hydrogen-bonding complex between HFP and secondary peroxy radical resulted in a large increase in the lifetime of these radicals.¹⁸ This variation was accompanied by a decrease in the corresponding EPR *g*-value. The progressive reduction in the rate of termination by peroxy radical as the concentration of HFP increased was explained by invoking the simple kinetic model advanced by Ingold and coworkers to justify the solvent effect observed in the rate of hydrogen abstraction from phenol by alkoxy radicals (see Scheme 3 and **Antioxidants in Chemistry and Biology**).¹⁹

According to this model, EPR decay traces are due to the self-reaction of non-hydrogen-bonded peroxy radical in rapid equilibrium with nonreactive hydrogen-bonded radicals. Analysis of decay traces in the presence of different amounts of HFP afforded K_{eq} . From the measure of K_{eq} at different temperatures, an enthalpy change of $-3.4 \text{ kcal mol}^{-1}$ was estimated for the formation of the hydrogen-bonded complex.

Further, nitroxide radicals are good hydrogen-bonding acceptors.²⁰ This favorable property has been used to modulate their reactivity in nitroxide-mediated living polymerization (NMP; see **Nitroxide-Mediated Polymerization and its Applications**).²¹

For other examples describing the effect of hydrogen bonding on radical reactivity, see **Thermochemistry and Hydrogen Transfer Kinetics**, **Antioxidants in Chemistry and Biology**, and **Nitroxide-Mediated Polymerization and its Applications**.

3 HALOGEN BONDING

The hydrogen atom is the most common electron acceptor site, and hydrogen bonding is the most frequently occurring noncovalent interaction in chemical and biological processes. Halogen atoms work equally well as acceptors and the interaction, which they give rise to, is characterized by several properties similar to those of the hydrogen bond.^{22–24} The term halogen bond (XB) is generally used for defining such noncovalent interactions involving halogens as electron acceptors. The general scheme $D \cdots X-Y$ thus applies to XB, in which X is the halogen (Lewis acid, XB donor), D is any electron donor (Lewis base, XB acceptor), and Y is carbon, nitrogen, halogen, etc.: halogen bonding to different XB donors can show a strength comparable to hydrogen bonding (in terms of equilibrium constants and other thermodynamic parameters).

Interest in molecular magnetic materials and emerging fields such as spintronics and quantum computing has inspired the study of X-bonding for directing the self-assembly of persistent nitroxide radicals to create supramolecular arrays with particular spin orientations.²⁵

Morishima *et al.* provided the earliest reports of the interactions between nitroxides and halogenated molecules, describing the effect of the radicals on the NMR chemical shifts of halogenated molecules.^{26–28} The interaction was explained in terms of a spin delocalization, or charge-transfer interaction, with the assistance of molecular orbital calculations. In 1990, Ingold and coworkers reported the observation of charge-transfer absorption bands when nitroxides were dissolved in polyhalogenated solvents.²⁹ Laser irradiation at wavelengths within these bands ‘instantaneously’ yields the corresponding oxoammonium halide and a carbon-centered radical via a photoinduced electron transfer followed by the loss of a halide ion (Scheme 4).

More recently, complexes of chlorine dioxide with piperidine nitroxides have been reported.^{30,31} In all cases, it is reasonable to hypothesize the

Scheme 4 Reaction scheme for the photodecomposition of the halogen-bonded complex between a dialkyl nitroxide and a CCl_4 .

formation of XB pre-reactive complexes that spontaneously undergo electron transfer and transform into oxoammonium salts. A crystallographic and magnetic study of 2-halo-substituted nitronyl nitroxides³² provided the first direct observation of $\text{O} \cdots \text{I}$ distances consistent with nitroxide X-bonding, although this term was not used to describe the interaction. Similarly, one of the two polymorphs of 4-(4-iodobenzylidenamino) TEMPO was reported to exhibit structural characteristics consistent with X-bonding and antiferromagnetic behavior.³³ Schollhorn *et al.* recently described the first deliberate investigation of nitroxides as X-bond acceptors, reporting the single-crystal X-ray analysis of a one-dimensional coordination polymer in which the dominant intermolecular forces are XB, involving the nitroxide radical 4-amino-TEMPO.³⁴ This report was rapidly followed by an EPR study of X-bonding between TEMPO and aliphatic and aromatic iodoperfluorocarbons in solution.³⁵ Formation of an X-bonded TEMPO was manifested primarily as an increase in the isotropic nitrogen hyperfine coupling a_N and by the marked broadening of the EPR lines observed when the nitroxide spectra were recorded in iodoperfluorocarbon solvents. As expected, these effects were greater for iodoperfluorocarbons than for bromoperfluorocarbons and iodocarbons. On formation of the XB, the unpaired spin density is in part transferred from the nitroxide moiety to the iodine atom, and at the same time, its delocalization on the nitrogen atom increases, giving rise to an increase in the nitrogen splitting. The origin of the line broadening may result either from unresolved iodine (^{127}I ; $I = 5/2$) hyperfine coupling or/and an increase in the rotational correlation time, a consequence of the increased hydrodynamic radius of the X-bonded nitroxide species. A ΔH^0 value of -7 kcal mol^{-1} was measured for the formation of the TEMPO/*n*- $\text{C}_8\text{F}_{17}\text{I}$ complex (Scheme 5).

Scheme 5 ΔH° value for the formation of the TEMPO/*n*-C₈F₁₇I complex.

DFT and MP2 calculations have subsequently been utilized to investigate the physicochemical properties^{36,37} of X-bonded adducts of TEMPO, including interesting deshielding effects consistent with spin transfer observed in the ¹⁹F NMR spectra of TEMPO/haloperfluorocarbon systems.³⁷

More recently, Micallef and coworkers investigated the EPR behavior in the presence of pentafluoriodobenzene of another class of nitroxide radicals: the isoindoline nitroxides.³⁸ Also in this case, the EPR spectrum obtained in the X-bonding donor solvent exhibited a dramatic increase in the spectral line width.

All these studies clearly demonstrated that persistent nitroxides are effective electron donors for the formation of halogen bonds with iodoperfluorocarbons. It is expected that in the near future other classes of persistent radicals will be investigated in order to design and synthesize functional molecular materials with potential application in the fields of molecular magnetism (see **Physical Properties of Thiazyl Radicals Toward Conductive and Magnetic Materials**), spintronics, and quantum computing.

4 HOST-GUEST COMPLEXES

The substantial change in NMR shieldings that one usually observes upon formation of host-guest complexes is the major reason why this technique has become by far the most important method for the characterization of such complexes.³⁹ A limitation of NMR is that it operates at rather low frequencies and possesses a relatively slow “time scale”. In the case of fast exchange, which is most common for host-guest complexes, one observes only one sharp signal at an intermediate mean-weighted position between the signals of free and complexed molecules.

On the other hand, EPR spectroscopy, which is usually characterized by a shorter time scale compared to that of complexation processes, gives

rise to separate signals from free and complexed species when the radical used as a probe shows different spectroscopic parameters upon complexation.⁴⁰ In this way, it is possible to extend the time range accessible to resonance methods of supramolecular chemical kinetics into the microsecond region⁴¹ and to create a possibility of discriminating different modes of complexation, leading to usually indistinguishable (by NMR) microequilibria.

The inclusion of radicals by host systems has been studied from time to time by EPR spectroscopy during the last 40 years. The majority of these reports have been concerned with very persistent species such as sterically protected nitroxides or aromatic radical ions. Different types of water-soluble host molecules (Figure 3) such as cyclodextrins,^{42–54} calixarenes,^{55–61} cucurbiturils,^{62–66} cryptophane,⁶⁷ and octamethoxy-*p*-cyclophane⁶⁸ were investigated.

Evidence for the formation of a complex between nitroxide radicals and host species is generally obtained on the basis of the changes of the hyperfine *a*_N coupling constants. For a dialkyl nitroxide, the isotropic nitrogen hfsc (comprised between 13.5 and 18 G) is known to be very sensitive to the nature of the environment: the greater the polarity⁶⁹ and/or the hydrogen-bonding capability of the medium²⁰ the more favoured will be the dipolar structure, bearing larger electron density on the oxygen and spin density on the nitrogen atom (Figure 4).

The partitioning of nitroxide probes in the hydrophobic environment of the host gives rise to a reduction in the value of nitrogen splitting, with the result that the resonance fields for the free and included species are significantly different from those of the nitroxide dissolved in water. Double integration of the two EPR signals affords equilibrium constants for the formation of the complex.

From the analysis of spectroscopic parameters of the included species, it was also possible to distinguish different geometries of inclusion. Such a discrimination was accomplished for the inclusion of the diphenylmethyl *tert*-butyl nitroxide into β -cyclodextrin by Kotake and Janzen.^{70–73} The EPR spectrum, recorded in the presence of β -CD, showed three different signals with different hyperfine splittings that were assigned to the radical in water and to the radical included in the cavity of the CD either from the phenyl side or from the *tert*-butyl side.

Figure 3 Some of the macrocyclic hosts investigated by EPR.

Figure 4 Resonance structures of dialkyl nitroxides.

By using the symmetric di-*tert*-amyl nitroxide, it was possible to demonstrate the formation of supramolecular structures with a higher level of organization in which the radical guest is able to template the formation of a complex with two molecules of β -cyclodextrin.⁷⁴

The persistence of the radical species made it possible to switch reversibly from 1:1 to 1:2 complexes many times by repeated acid–base treatments (as depicted in Figure 5) or by changing the temperature without occurrence of any side reaction. These 1:2 complexes represented the first examples of three-component, organic free radical

supramolecular entities, which can be reversibly formed by changing pH or temperature.

Benzyl *tert*-butylnitroxide and related nitroxides (reported in Figure 6) deserve a special mention. These radical probes, in the presence of different hosts, afforded easily including complexes, as indicated by the decrease in the nitrogen hyperfine splitting, a_N (due to the less polar environment of the host cavities), and from the change in the coupling to the benzyl protons, $a_{2H\beta}$ (due to conformational changes upon complexation).

Moreover, inclusion created a significant difference in the resonance field of the wing lines of each β -proton triplet ($M_1(H_\beta) = \pm 1$) of the included and free species with all kinds of host systems so far investigated, and in many cases the EPR spectra showed a strong linewidth dependence on temperature, indicating that the lifetime of formation and dissociation of the supramolecular complexes is in the range characteristic of the EPR spectroscopy.

Figure 5 Schematic representation of the equilibria taking place in the presence of di-*tert*-amyl nitroxide and β -cyclodextrin.

Figure 6 Schematic representation of the equilibrium taking place in the presence of β -cyclodextrin and EPR spectrum of benzyl *tert*-butyl nitroxide recorded in water in the presence of β -cyclodextrin with the corresponding theoretical simulation.

This favorable feature enabled measurement, by EPR, of the rate constants for the complex association (k_{ass}) and dissociation processes (k_{diss}) with different host systems.^{56,62,75–79}

In order to expand the use of EPR to study complexes of CDs with diamagnetic molecules, persistent nitroxide units have been covalently attached to cyclodextrin rims (Figure 7).^{80–84} In general, the aqueous solutions of spin-labeled CDs show typical nitroxide EPR spectra with the high field line broadened owing to restricted tumbling. Although the EPR parameters of these materials are not very sensitive to the complexation of small molecules, the formation of large host–guest complexes leads to substantial reduction in the rate of tumbling.

Spin-labeled CD containing two 4-carboxy-TEMPO groups attached to adjacent glucose units

Figure 7 Schematic representation of a spin-labeled cyclodextrin.

or separated by two glucose units have also been reported and characterized by EPR.⁸⁵

Quite recently, spin trapping experiments have been performed in the presence of cyclodextrins or cucurbiturils.⁸⁶ A significant enhancement in adduct stability and a partial protection against glutathione peroxidase- and ascorbate anion-induced

Figure 8 EPR spectrum of the reported α -carboxyl radical in the presence of 2-hydroxyl- β -cyclodextrin. [Lucarini *et al.* (1996). Ref. 87. Reproduced by permission of The Royal Society of Chemistry. <http://dx.doi.org/10.1039/CC9960001577>.]

reduction are generally observed. The reader is invited to consult **Spin Labels and Spin Probes** for a complete discussion on this topic.

Although the majority of host–guest systems have been concerned with very persistent radicals, inclusion inside CD cavity of transient carbon-centered radicals as that shown in Figure 8 has been reported by using EPR spectroscopy.⁸⁷ This radical was generated in aqueous solution, using the flow technique, in which the solution passes through the microwave cavity about 60 ms after mixing the reagents. In the presence of CDs, the spectra of all radical species showed additional signals, which were assigned to the species included in CD.

Inspection of spectral parameters of the radical inside the hydrophobic cavity of CD shows that the values of the benzyl proton splitting, a_{2H} , of the included (27.9 G) and free species (23.1 G) are considerably different. These data demonstrate that inclusion leads to changes in the conformation adopted by the radical as reflected by the change in the hyperfine splitting of the hydrogen β atoms to the radical center, whose magnitude depends on the conformation adopted by the

radical. In general, the changes in conformation and unpaired-electron distribution that accompany inclusion of a transient radical could have significant effects on the regio- and stereochemistry of intramolecular reactions of guests, as compared with the same reaction of unbound radicals. With the only exception of a paper by Fukunishi *et al.* showing that inclusion inside cyclodextrin cavity promotes radical cyclization of *o*-(2-propenyloxy)- and *o*-(2-propynyloxy)benzenediazonium ions,⁸⁸ the monomolecular reactivity of free radicals inside cyclodextrins remains totally unexplored. However, it should be kept in mind that under free radical conditions the potential for a number of different cyclodextrin radicals to be formed exists and thus CDs cannot be treated as inert hosts.^{89–91}

Encapsulation inside the cavity of cucurbiturils or cyclodextrin can be used to increase the stability of aromatic radical cations. It has been shown by UV–Vis absorption, EPR, and electrochemical measurements that encapsulation by cucurbit[7]uril increases the thermodynamic and kinetic stability of the radical cation of the oligoaniline reported in Figure 9.⁹²

The stabilization is even more pronounced when many cucurbituril macrocycles are introduced onto a long radical cation polyaniline chain. This complexation leads to a slower attenuation rate and a smaller attenuation ratio of the radical cation, as well as lower first oxidation and reduction potentials compared to those of free polyaniline.⁹³

The effect of methylene blue (MB, Figure 10) encapsulation in cucurbit[7]uril on triplet excited-state behavior and singlet oxygen (1O_2) generation has also been recently studied by using laser flash photolysis and time-resolved near-IR luminescence spectroscopy. The lifetime of the triplet excited state of MB is longer in the cucurbit[7]uril cavity with respect to aqueous MB. Cucurbituril also protects the dye triplets from

Figure 9 Radical cation deriving from a polyaniline.

Figure 10 Structure of methylene blue (MB).

quenching by oxygen, reducing the quenching rate constant of circa one order of magnitude (from 2.6×10^9 to $0.2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$).⁹⁴

5 SELF-ASSEMBLY

5.1 Self-Assembled Radicals

Self-assembly is generally defined as “the spontaneous and reversible organization of molecular units into ordered structures by noncovalent interactions”.⁹⁵ Because of these weak noncovalent interactions the amount of energy required for forming or destroying self-assembled structure is relatively small when compared to covalent interactions. Thus, one important feature of supramolecular self-assembly is its dynamic nature, which permits the preparation of functional materials, the physical properties of which can be reversibly modified by the action of appropriate external stimuli such as light or temperature.

Organic radicals that have no particular intermolecular interaction can be accommodated by self-assembled processes to give ordered structures in which two or more radical centers are enforced to be close to each other, inducing spin–spin interactions. Since in a self-assembled polyradical, the geometry of the radicals is fixed only by weak noncovalent interaction, in principle, the spin–spin interaction can be tuned and controlled by external stimuli.

Self-assembled polyradicals with unpaired electron spins in their frameworks have been prepared only very recently. This is mainly because of difficulties in introducing stable organic radicals at the core of the host frameworks. Fujita and coworkers reported the self-assembly of a radical cage containing multiple spin centers around a cavity suitable for guest inclusion.⁹⁶ They showed that persistent verdazyl radicals quantitatively self-assembled into the large spin cage shown in Figure 11 upon treatment with a Pd(II) complex. Similar to diamagnetic cages based on the triazine-cored complexes,⁹⁷ the reported spin cage is capable of binding neutral guests within the cavity in aqueous media.

A different example of open-shell moieties ordered by a supramolecular architecture showing new magnetic properties and based on lipophilic guanosines has been reported.^{98,99} Lipophilic

Figure 11 Self-assembled verdazyl-based spin cage.

guanosines are very versatile self-assembling units. In the presence of alkali cations, they spontaneously self-associate to give quartet-based columnar structures.¹⁰⁰ As it is possible to functionalize the guanosines in the eighth position and/or at the sugar hydroxy functions, they are ideal scaffolds to locate functional units in pre-programmed positions, inside highly ordered architectures. Graziano *et al.* showed that in the presence of K^+ , guanosine derivatives containing the persistent radical unit 4-carbonyl-2,2,6,6-tetramethylpiperidine-1-oxyl are able to self-assemble to give octameric species showing strong spin–spin interactions (Figure 12). Interestingly, it is possible to reversibly switch between discrete quartet-based assemblies and octamers by simply adding or removing metal cations. In this way, it is possible to reversibly control the intermolecular spin–spin interactions (Figure 12).

5.2 Spin Label to Investigate the Properties of Self-Assembled Monolayers Protecting Gold Nanoparticles

One of the most important nanosized materials is represented by metal nanoparticles (NPs) in the form of colloids and nanocrystals that are

Figure 12 Assembly of a radical-armed guanosine derivative in the presence of alkali metal cations.

typically 1–50 nm in diameter.¹⁰¹ The surface of metal NPs may be passivated by organic ligands, forming a self-assembled monolayer (SAM) on a curved surface.^{102–105} These systems are usually named monolayer-protected clusters (MPCs). SAMs on NPs simultaneously stabilize the reactive metal and present organic functional groups at the particle–solvent interface. Tailored organic surfaces on metal NPs are useful for applications in nanotechnology, in different fields of material science, chemistry, biology, and medicine.

Persistent nitroxides radicals have been anchored to the surface of gold NPs. The first example has been reported in 1998 by Murray and coworkers who were able to couple 4-amino TEMPO with an MPC (see Figure 13) having ω -carboxylic acid groups. In this example, each gold cluster contained circa 13 nitroxide units.¹⁰⁶

AuNPs protected by weakly bound ligands such as phosphines, amines, or short alkyl thiolates can be transformed to spin-labeled NPs by simply mixing them with a disulfide diradical.^{107,108}

The first example of TEMPO being immobilized on magnetic NPs was reported in 2008.¹⁰⁹ TEMPO was covalently bonded to carbon-coated/Co FNPs, which have excellent magnetic properties. The NPs were shown to be highly active for the oxidation of alcohols using stoichiometric amounts of NaOCl and were cycled 14 times with no apparent loss of catalytic activity. More recently, TEMPO was immobilized on iron oxide (Fe_3O_4) superparamagnetic NPs by employing strong metal-oxide chelating phosphonates and azide/alkyne “click” chemistry.¹¹⁰ This simple preparation yields recyclable TEMPO-coated NPs with good TEMPO

Figure 13 Schematic representation of TEMPO functionalized monolayer-protected metal nanoparticles.

loadings. They have excellent magnetic response and efficiently catalyze the oxidation of a wide range of primary and secondary alcohols to aldehydes, ketones, and lactones under either aerobic acidic Mn(II)/Cu(II) or basic NaOCl conditions (see **Nitroxides in Synthetic Radical Chemistry**).¹¹¹

By using nitroxide-labeled gold NPs and EPR spectroscopy Chechik and coworkers were able to investigate ligand dynamic on the gold surface and the ligand place-exchange reactions.^{112–115} The lateral mobility of the thiolate ligands on the surface of AuNPs has also been probed by EPR spectroscopy. This was achieved by using bisnitroxide ligands, which contained a disulfide group (to ensure attachment to the Au surface) and a cleavable ester bridge connecting the two spin-labeled

branches of the molecule.^{116,117} EPR spectroscopy has also been employed for accessing interfacial surface electrostatics of ligand-protected AuNPs.¹¹⁸

The properties of NPs can also be investigated by doping them with stable radicals not only in the form of covalently bonded compounds (spin labels) but also as added molecules (spin probes). Actually, EPR spectroscopy was employed for the investigation of the interaction between stable nitroxide radicals, such as TEMPO, TEMPOL, and unprotected AuNPs of various sizes.¹¹⁹ Unfortunately, the exchange interactions between the unpaired electrons of the adsorbed organic radicals and conduction-band electrons of the metallic particles were found to hide the EPR signal. However, in the presence of an organic monolayer covering the gold core of the NP, the addition of suitable spin probes gives rise to relatively persistent EPR signals that have been used to investigate the properties of self-assembled organic monolayers. These investigations rely on a series of nitroxide probes, obtained by *in situ* oxidation of amine precursors, based on the benzyl *tert*-butyl nitroxide moiety. With this family of probes the following systems were investigated:

1. Gold nanoparticles composed of an amphiphilic thiolate (C8-TEG) containing a hydrocarbon chain close to the gold surface and a poly(ethylene glycol) chain which provides high solubility in water and other polar solvents of different sizes.^{120,121}
2. Water-soluble AuNPs protected by a monolayer of fluorinated amphiphilic thiols (F8-PEG)

containing a perfluorinated portion and a short poly(ethylene glycol) unit.¹²²

3. Mixed monolayers composed of thiols that differ by an alkyl- or a perfluorinated chain.¹²³

These results have been recently reviewed.¹²⁴

5.3 Mechanical Interlocking of Free Radicals

Probably, one of the most attractive aspects of self-assembly is represented by the mechanical interlocking of molecules.^{125,126} Mechanical interlocking means that two or more species became connected to each other, not by chemical bonds, but rather are threaded through or around one another to form a single chemical species. The assemblies are generally sustained by supramolecular interactions between the individual, covalent components. Species that are linked in this way are said to be topologically connected. In order for compounds to be truly topologically connected, a chemical bond must be broken in order to extract the individual components of the assembly from each other. The great interest in such systems derives for the use as nanoscale molecular machines and molecular electronic devices.

One of the most important classes of interlocking structures is represented by rotaxanes. A rotaxane consists of a linear molecule which is threaded through a ring with the ends of the thread, or axle, capped in such a manner that the ring cannot slip off (Figure 14). Another example of topologically

Figure 14 Schematic representation of a rotaxane and a catenane.

Figure 15 Structure of the switchable rotaxane reported in Ref. 134. [Bissell *et al.* (1994). Reproduced from Ref. 134. Copyright Macmillan Publishers Ltd, 1994.]

Figure 16 The chemically and electrochemically triggered redox switching of a catenane. [Asakawa *et al.* (1998). Ref. 135. Copyright Wiley-VCH Verlag GmbH & Co. KGaA. Reproduced with permission.]

connected species is represented by catenanes that are mechanically interlocked macrocycles akin to links in a chain.

Rotaxanes are not merely chemical curiosities but they also have the potential to act as molecular machines.^{127–129} Rotaxane threads can be designed in such a manner that they contain two different binding sites for the macrocycle. The preference for the macrocycle to bind to one site or the other can then be influenced by external factors, either chemically,¹³⁰ electrochemically,¹³¹ or photochemically.¹³² The ring can therefore be moved back-and-forth along the axle and such functional assemblies are known as molecular shuttles.

Persistent radical ions represent important functionalities that have been employed in different electrochemical-driven molecular shuttles. Macrocycles can be induced to move from one binding site to another of the axle by providing or subtracting an electron to the axle thus giving rise to the corresponding radical ion. A first example is provided by rotaxanes incorporating cyclobis(paraquat-*p*-phenylene) (CBPQT⁴⁺)¹³³ as their ring component and two electron-rich aromatic units as the two different recognition sites on their axial component (Figure 15).¹³⁴

The preferred location of the wheel is in proximity to the benzidine part. Ring shuttling to the biphenol part can be induced electrochemically by oxidation of the benzidine part to its radical cation. In this case, charge repulsion with the fourfold positively charged wheel induces ring migration to the

biphenol station. The process is reversible, and the reduction of the benzidine radical leads back to the resting state.

Another example is provided by catenanes incorporating CBPQT⁴⁺ as their ring component and two electron-rich aromatic units tetrathiafulvalene (TTF) and 1,5-dioxynaphthalene (DNP) as the two different recognition sites (Figure 16).¹³⁵

One electron oxidation of the TTF moiety to the corresponding radical cation provokes circumrotation of the catenane rings leading to a structure where the cyclophane wheel with its two paraquat units is located in proximity to the DNP part of the crown ether ring. Again the process is reversible and the reduction of TTF to its normal form shifts back the ring to its resting state.

Electrochemically switchable molecular shuttles based on the reduction of the axle to the corresponding radical anion has also been reported.¹³¹ These rotaxanes contain succinamide and naphthalimide hydrogen-bonded stations for a benzylic amide macrocycle (Figure 17).

In its resting state, the rotaxane has the macrocycle hydrogen bonded to the succinamide unit. Electrochemical reduction of the naphthalimide station to the corresponding radical anion increases the HBA ability of the imide units to such a degree that translocation of the macrocycle is observed.

Very recently, Stoddart and coworkers introduced a new type of interaction based on viologen radical cations (V^{•+}) that paves the way to the preparation of very sophisticated molecular devices.^{136–138}

Figure 17 The electrochemically switchable, hydrogen-bonded molecular shuttle reported in Ref. 131. [Altieri *et al.* (2003). Reprinted with permission from Ref. 131. Copyright 2003 American Chemical Society.]

Figure 18 The attraction of positively charged radicals offers new opportunities for molecular machines made from interlocked molecules. Reduction leads to the formation of a stable complex between a viologen and the bis-viologen ring. [Anderson (2010). Reproduced from Ref. 137. Copyright Macmillan Publishers Ltd, 2010.]

Figure 19 Schematic representation of the paramagnetic rotaxane containing α -cyclodextrin reported in Ref. 139.

Viologen radical cations are known to undergo dimerization and the formation of dimers $(V^{\bullet+})_2$ can be used as a new interaction for controlling switching between different states in switchable mechanically interlocked molecules. Stoddart and coworkers synthesized a molecule consisting of a ring threaded on a dumb-bell-shaped rod, such that the location of the ring along the length of the dumb-bell can be switched between three different positions just by changing the oxidation state of the compound. In the resting form, the ring prefers to sit around the most electron-rich TTF unit; oxidation of this TTF makes the ring prefer to sit on the naphthalene, whereas reduction makes the ring relocate to the central viologen. All these switching processes are fully reversible. The idea is summarized in Figure 18.

Sterically hindered nitroxides have been employed as bulky capping groups in the preparation of paramagnetic rotaxanes. In the first example,¹³⁹ the rotaxane is made from molecules having an alkyl chain flanked by 2,2,6,6-tetramethylpiperidine-*N*-oxyl (TEMPO) groups (Figure 19). Complexation of sebacoyl chloride by α -cyclodextrin followed by reaction with 4-amino-TEMPO resulted in the trapping of the cyclodextrin, threaded by the alkyl chain, thus generating the rotaxane structure. The room temperature EPR spectrum of the paramagnetic rotaxane (in water $a_N = 17.05$ G, $g = 2.0057$) consists of three lines as expected for a nitroxide

biradical in the extended conformation in which the TEMPO fragments behave as two single nitroxide radicals.

Very recently, the first example of paramagnetic rotaxane containing two cucurbit[6]urils (CB6) as the wheels has also been reported and characterized both by EPR and NMR spectroscopy.¹⁴⁰ Synthesis of the rotaxane was achieved using CB6 as the catalyst in the 1,3-dipolar cycloaddition between a nitroxide functionalized bearing an alkyne group and an aromatic chain containing azide functionalities to give 1,4-disubstituted triazole (Figure 20).

Lucarini and coworkers¹⁴¹ have recently synthesized a [1]rotaxane-type¹⁴² nitroxide-appended β -cyclodextrin with improved resistance to glutathione reduction (Figure 21). In this self-included molecule, the nitroxide functionality is mechanically trapped inside the cavity of CD by a covalent link with one of the CD rims. The TEMPO fragment has an approximately cylindrical shape whose diameter is about 8.5 Å, well above the internal diameter of the β -CD smaller rim (< 6.2 Å). On the basis of this, it was concluded that the barrier for the escape of the nitroxide moiety from the CD cavity must be significantly high, and the presence of a reversible equilibrium between the open and threaded forms of self-complex was excluded.

6 SUPRAMOLECULAR CONTROL OF RADICAL REACTIVITY INSIDE ZEOLITES

During the last years, zeolites have been largely examined as reaction media to control the product distribution of radical reactions.¹⁴³ Interest in the chemistry of radicals adsorbed on zeolites derives from the observation that the products of radical–radical reactions, which are nonselective in solution, can be made selective and can be controlled by supramolecular effects. Zeolites¹⁴⁴ are crystalline aluminosilicates constituted by oxygen (corner) sharing tetrahedral AlO_4 and SiO_4 groups that form a rigid three-dimensional network termed the zeolite framework. Their internal surface consists of an interconnected network of cylindrical channels (diameter circa 5.5 Å) and intersections (diameter circa 9 Å). The external surface is composed of a nonporous framework and pore openings. The pore openings on the external surface provide access to the channels and intersections of the internal surface. As a result, only molecules whose size/shape characteristics allow penetration into the holes and whose mobility allows diffusion inside the channels will be adsorbed efficiently on the internal surface.

The carbon radicals produced by photoexcitation are inert toward reaction with the zeolite framework. This feature allows the study of the effect of confined space on radical–radical reactions, which determines the observed products and radical persistence. The restricted mobility within zeolite pores limits the tendency of radicals, radical cations, or other reactive intermediates to undergo radical-destroying bimolecular reactions and prevents access to adventitious reagents (e.g., water and oxygen) that would cause their decay in solution. As a result, the trapped reactive intermediates can have lifetimes long enough to be studied by conventional spectroscopic techniques usually reserved for ordinary stable molecules. Carbon-centered radicals, for example, can live several hours and be studied by EPR or fluorescence on zeolite surfaces.^{145–148} In particular, the benzyl radical persists with a half-life of about an hour, whereas the diphenylmethyl radical is persistent for several days. The addition of air to a sample of DPM causes a peroxy radical spectrum to appear.^{145,146} Remarkably, when the sample

is vacuum degassed, the EPR signal of the diphenylmethyl radical reappears, showing that the addition of molecular oxygen is reversible.¹⁴⁵ Investigations of the photochemical reactions of molecules adsorbed on zeolites have provided insights into the supramolecular structure and dynamics of intermediates produced by photolysis.^{149–151}

Chemical transformation different from that observed in solution has also been observed. Actually, photolysis of aryl chlorides adsorbed gives rise to radical cations and the constraints imposed by the channels shift the reactivity from the C–Cl bond to the O–R bond.¹⁵²

7 CONCLUSION

The reported examples showed not only that supramolecular chemistry can be used to control the reactivity of organic free radicals but also that free radicals are important scaffolds to locate functional units in pre-programmed positions, inside highly ordered architectures. In particular, redox-active radical switches, which allow for direct and easily reversible control on reduction as well as on oxidation, could be forerunners to the development of molecular electronic devices.

At the same time, EPR spectroscopy has been extensively used for detecting and identifying non-covalent assemblies in solution and for clarifying their structure and properties. Although paramagnetic probes must be added to the samples, the reported examples provided considerable information on the properties of the noncovalent systems that are difficult to obtain with more common techniques. It is expected that this technique will significantly improve our ability to study more deeply supramolecular systems.

Silanes as Reducing Reagents in Radical Chemistry

Chrysostomos Chatgililoglu¹ and Vitaliy I. Timokhin²

¹ISOF, Consiglio Nazionale delle Ricerche, Bologna, Italy and ²Department of Chemistry, University of Wisconsin-Madison, Madison, Wisconsin, USA

1 INTRODUCTION

Silyl radical reactions can often be found as key steps of complex synthetic procedures oriented toward the construction of very different structures, spanning from natural products to silicon surfaces. In the late 1980s, Chatgililoglu introduced tris(trimethylsilyl)silane, (TMS)₃SiH, or TTMSS, as radical-based reducing agent for functional group modifications and mediator of sequential radical reactions. (TMS)₃SiH won the Fluka's reagent of the Year Prize in 1990 for its use in radical processes as a valid alternative to the toxic Bu₃SnH (see **Tin Hydrides and Functional Group Transformations**).¹ (TMS)₃SiH has found multiple applications in organic synthesis as well as in polymers and materials science.² Both its low toxicity and the mild reaction conditions rendered (TMS)₃SiH the reagent of choice for the reduction of organic halides, selenides, and activated hydroxy- and carboxy groups, also in aqueous media. The unique reactivity of (TMS)₃SiH has also been exploited in cascade reactions leading to complex molecular scaffolds in a single step. The entire radical chemistry of (TMS)₃SiH and related organosilanes has been the subject of periodical reviews^{1–6} and was summarized in the book *Organosilanes in Radical Chemistry*.⁷ The purpose of this article is

to give an overview of the relevance of organosilanes as radical-based reducing agents in organic synthesis.

2 SILANES AS RADICAL-BASED REDUCING AGENTS

The majority of radical reactions of interest to synthetic chemists are chain processes under reductive conditions (see **Basic Concepts on Radical Chain Reactions**).⁸ The reduction of a functional group by silicon hydride is shown in Scheme 1 as an example of a chain process.^{1,7} Initially, R'₃Si· radicals are generated by some initiation process. In the propagation steps, the removal of the functional group Z in the organic substrate (RZ) takes place by the action of the R'₃Si· radical via a reactive intermediate or a transition state represented by [RZ(·)SiR'₃]. A site-specific radical (R·) is generated, which then reacts with the silicon hydride and gives the reduced product (RH), together with “fresh” R'₃Si· radicals to reinitiate the chain. The chain reactions terminate by radical–radical combination or disproportionation reactions.

The hydrogen abstraction step from the Si–H moiety of silanes is fundamentally important for these reactions. Kinetic studies have been performed with a large variety of radicals toward (TMS)₃SiH

Scheme 1 Mechanism of the reduction of a functional group by silicon hydride.

(see **Radical Kinetics and Clocks**).⁹ In Figure 1, the scale of rate constants of hydrogen abstraction from a few group 14 hydrides by primary alkyl radicals at 80 °C is provided. The rate constant for (TMS)₃SiH is only ~5 times slower than that of Bu₃SnH. The contribution of TMS groups on the reactivity of (TMS)₃SiH can be appreciated in the analogous silane where one TMS group is replaced by Me,^{2,6} which results to have a 10 times slower rate constant. The couple (TMS)₃SiH/thiol functioning as a free-radical reducing system will be discussed later (Section 2.1.4).

2.1 The (TMS)₃SiH Reagent

2.1.1 Removal of Functional Group

(TMS)₃SiH is an effective reducing agent for the removal of a variety of functional groups. Several

examples are shown in Schemes 2–4. The most popular thermal initiator is azobisisobutyronitrile (AIBN), with a half-life of 1 hour at 81 °C. Other azo compounds are also used from time to time depending on the reaction conditions. Et₃B in the presence of very small amounts of oxygen is an excellent initiator for lower temperature reactions (down to –78 °C).

Examples of dehalogenation are shown for chloride **1**,¹⁰ bromide **2**,¹¹ and iodide **3**,¹² as well as for dichloride **4**.¹³ (Scheme 2). The reduction of dichloride represented the key step in the total synthesis of dactomelynes, a group of natural products isolated from a marine organism. The use of (TMS)₃SiH at room temperature allowed the monochloride to be obtained in high yield and stereoselectivity ($\beta : \alpha = 13 : 1$), whereas other radical-based reducing systems failed.¹³ In this respect, the stereoselective reduction of *gem*-dichlorides by (TMS)₃SiH or Bu₃SnH was previously reported, evidencing the different spatial shapes of the two reagents.¹⁴ This shows that the silane has a stronger preference than tin hydride to transfer a hydrogen atom from the less hindered side of the molecule.

The removal of functional groups is beyond dehalogenation. Reductive removal of chalcogen groups such as the selenide **5** can be obtained (Scheme 3).¹⁵ For the removal of a hydroxy group, the strategy starts from a thiocarbonyl derivative (e.g., *O*-arylthiocarbonate, *O*-thioxocarbamate, thiocarbonyl imidazole, or xanthate) or a selenocarbonate. Two examples of thiocarbonyl derivative are provided using the *O*-phenylthiocarbonate **6**¹⁶ and xanthate **7**.¹⁷ The latter is the last step of a multistep synthesis toward the natural product ventricos-7(13)-ene, a triquinane having a remote exo-methylene group. The authors reported that the Barton–McCombie reduction of xanthate **7** using

Figure 1 Rate constants for H-atom abstraction from a variety of reducing systems by primary alkyl radicals at 80 °C.²

Scheme 2 Dehalogenation by reaction with $(\text{TMS})_3\text{SiH}$ (PhthN = *N*-phthalimido group).

TTMSS as the hydride source have proven to be critical: the silane by-products could be removed by treatment of the reaction mixture with tetrabutylammonium fluoride (TBAF), whereas they were unable to adequately purify the natural product when using the conventional organotin hydride reagent.¹⁷ Also for the selenocarbonate **8**, the deoxygenation was found effective, and it was achieved with an 87% efficiency from the alcohol.¹⁸

1,2-Diols can be transformed into olefins using the cyclic thiocarbonates or bisdithiocarbonate derivatives. Scheme 4 shows the olefination from cyclic thiocarbonate **9** where the *E*-isomer is more favored in the presence of the bulky *tert*-butyldimethylsilyl (TBDMS) group.¹⁹ The choice of functionalization of primary alcohols prior to the reaction with $(\text{TMS})_3\text{SiH}$ plays an important role. The hydroxyl group removal of primary alcohols can be achieved from a thiocarbonyl derivative such as the *O*-phenylthiocarbonate derivative **10**, using a slightly higher temperature than that for the deoxygenation of secondary alcohols (Scheme 3).²⁰ On the other hand, the phthalimido *D*-ribofuranose derivative **12** affords the *D*-erythrose **13** in good yield via the intermediacy of an alkoxyl radical

that undergoes a β -fragmentation prior to hydrogen abstraction.²¹ Similar reaction was obtained from the *D*-xylo to *L*-threose derivative.²¹

A variety of acyl derivatives (such as acyl chlorides, phenylseleno esters, or *N*-hydroxypyridine-2-thione esters) can be used for decarbonylation and reductive decarboxylation with $(\text{TMS})_3\text{SiH}$.²² The example of phenylseleno ester **14** afforded the decarbonylated β -lactam in good yield (Scheme 5).²³ The *N*-hydroxypyridine-2-thione ester **15** was used in the key step to construct the chiral *cis*-cyclopropane structure in compounds designed as antidopaminergic agents.²⁴ The observed high *cis* selectivity is due to the hydrogen abstraction from the sterically demanding $(\text{TMS})_3\text{SiH}$, which occurs from the less hindered site of the intermediate cyclopropyl radical. Hydrolysis of the methyl ester followed by decarbonylation at the C2 position of hexahydropyrroloindole (+)-**16**, afforded the desired tricyclic product in 84% yield and >99% ee.²⁵ The reduction of the isocyanide **17** is considered a smooth route for the deamination of primary amine obtained via formylation and dehydration.^{1,26}

Scheme 3 Removal of functional groups by reaction with $(\text{TMS})_3\text{SiH}$.

Scheme 4 Removal of functional groups by reaction with $(\text{TMS})_3\text{SiH}$.

Scheme 5 Removal of functional groups by reaction with (TMS)₃SiH.

Synthesis of secondary amines can be achieved either by replacement of a pyridinium moiety (**18**) with hydrogen²⁷ (Scheme 5) or by reduction of nitroxides.²⁸

The radical-based reductions with TTMSS have been expanded toward technological applications. Examples are the radical-based transformations in a microstructured reaction device in which deoxygenation and dehalogenation reactions

are found to be highly efficient (see **Radical Chemistry by Using Flow Microreactor Technology**),²⁹ the cleavage from resin-bound selenium and tellurium derivatives,³⁰ or the removal of terminal thiocarbonyl group from polystyrene.³¹

TTMSS is useful for the reduction of phosphine sulfides and phosphine selenides under free-radical conditions to give the corresponding phosphines or, after treatment with BH₃·THF (THF = tetrahydrofuran), the corresponding phosphine–borane

complex in good to excellent yields.³² Stereochemical studies on P-chiral phosphine sulfides showed that these reductions proceed with retention of configuration. This desulfidation protocol has recently been applied with success to the synthesis of bulky phosphines,³³ (Z)-1,2-diphosphino-1-alkenes,³⁴ and 1-thio-2-phosphino-1-alkenes.³⁵ An example of desulfidation of phosphine sulfide **19** is given in Scheme 6. During the desulfidation, no isomerization of the C–C double bonds took place. It is worth underlining that, in these reactions, the ejected silyl-ethyl radical undergoes a fast 1,2-migration of silyl group from silicon to sulfur, affording a new silyl radical, which either reacts with (Me₃Si)₃SiH to give **20**, completing the reaction cycle (Scheme 6), or replaces the (Me₃Si)₃Si• radical in the reaction sequence.³⁶

2.1.2 C–Si Bond Formation

The radical-based hydrosilylation of carbon–carbon double bonds by (TMS)₃SiH is an important class of reactions affording silanes **21** (Scheme 7).^{2,6,7} The initially generated silyl radical adds to the double bond to give a radical adduct **22**, which then reacts with the silicon hydride and gives the addition product, together with “fresh” silyl radicals to continue the chain. Rate constants for the reaction of (TMS)₃Si• radical with a variety of monosubstituted olefins were measured by laser flash photolysis techniques.^{26,37} Hydrosilylation of monosubstituted and *gem*-disubstituted olefins is an efficient process, which occurs with high regioselectivity (anti-Markovnikov) in the case of both electron-rich and electron-poor olefins.³⁸

Scheme 6 Desulfidation of phosphine sulfides.

Scheme 7 Hydrosilylation of alkenes by (TMS)₃SiH.

Analogous reactions were performed using tetrahydropyran as the solvent and 2,2'-azobis(dimethyl valeronitrile) as the initiator at 70 °C,³⁹ as well as in water using 1,1'-azobis(cyclohexane carbonitrile) at 100 °C (*vide infra*).⁴⁰ For cis- or trans-disubstituted double bonds, hydrosilylation was still an efficient process, although it requires slightly longer reaction times and an activating substituent.³⁸

The addition of (TMS)₃Si• radical to 1,2-dialkyl substituted olefins is reversible. This radical behavior can be noteworthy also from a synthetic point of view. An example based on the isomerization of 1,5,9-cyclododecatriene (**23**) is shown in Scheme 8.⁴¹ The final isomeric composition of 78:20:2 for (*E,E,E*)-**23**:(*Z,E,E*)-**23**:(*Z,Z,E*)-**23**, which is independent of the starting isomer or isomeric mixture, was reached in 5 hours by using (TMS)₃SiH/*t*-BuOOBu-*t*/143 °C and the yield was ~80%.

Radical-mediated silyldesulfonylation of various (*E*)-vinyl sulfones **24** (R = alkyl or aryl) with (TMS)₃SiH provides access to (*E*)-vinyl silanes **25** (Scheme 8).^{42,43} These highly stereoselective reactions presumably occur via a radical addition followed by β -scission with the ejection of the PhSO₂• radical. Hydrogen abstraction from (TMS)₃SiH by the PhSO₂• radical completes the cycle of these chain reactions. Such silyldesulfonylation provides an alternative to the hydrosilylation of alkynes with (TMS)₃SiH that affords mainly (*Z*)-vinyl silanes

(*vide infra*). Upon oxidative treatment with hydrogen peroxide in basic aqueous solution, compound **25** undergoes Pd-catalyzed cross-couplings with aryl halides.^{42,43} In an analogous process, the reactions of unsubstituted and 2-substituted allyl phenyl sulfides **26** with (TMS)₃SiH give a facile entry to allyl tris(trimethylsilyl)silanes **27** in high yields (Scheme 8). In this case, the addition of (TMS)₃Si• radical to the double bond is followed by β -scission with ejection of a thiyl radical, thus affording the transposed double bond. Hydrogen abstraction from (TMS)₃SiH by PhS• radical completes the cycle of these chain reactions.⁴⁴

The addition of (TMS)₃SiH to a number of mono-substituted acetylenes was also studied in some detail.^{38,45} These reactions are highly regioselective (anti-Markovnikov) and give terminal (TMS)₃Si-substituted alkenes in good yields. High cis or trans stereoselectivity is also observed, depending on the nature of the substituents at the acetylenic moiety. For example, the reaction of the alkynes **28** and **29** with (TMS)₃SiH, initiated either by Et₃B at room temperature^{38,45} or by thermal decomposition of di-*tert*-butyl peroxide at 160 °C,⁴⁶ gave the same results (Scheme 9). These reactions proceed also without solvent as shown for the case of alkyne **30**.^{47,48}

The hydrosilylation reactions are of interest also because they represent a model reaction for the functionalization of silicon surfaces using radical chemistry.^{2,6} Indeed, radical reactions have

Scheme 8 Various reactions for which the key step is the addition of (TMS)₃Si• radical to the C–C double bonds.

Scheme 9 Hydrosilylation of alkynes by $(\text{TMS})_3\text{SiH}$.

been found to be most convenient for achieving organic modifications of hydrogen-terminated silicon surfaces. The two flat surfaces H-Si(111) and H-Si(100)-2 $\times$ 1 resemble $(\text{Me}_3\text{Si})_3\text{SiH}$ in that the three silicon atoms are attached at the SiH moieties.^{49,50} Therefore, it is not surprising that several $(\text{Me}_3\text{Si})_3\text{SiH}$ reactions, in particular activated alkenes and alkynes, have been adopted and applied to surfaces, and that mechanistic schemes are often proposed in analogy with $(\text{Me}_3\text{Si})_3\text{SiH}$ radical chemistry (see **Silicon Radical Surface Chemistry**).^{51,52}

2.1.3 Reaction with Molecular Oxygen

The reaction of $(\text{Me}_3\text{Si})_3\text{SiH}$ with oxygen is of considerable importance. From our initial studies, we found that this reaction occurs spontaneously and slowly at ambient temperature to form siloxane as the sole product.⁵³ When $(\text{TMS})_3\text{SiH}$ was treated with a mixture of $^{16}\text{O}_2$ and $^{18}\text{O}_2$ and the crude products were analyzed by mass spectrometry, similar label distributions were observed in the products as in the reactants for both cases, indicating an intramolecular mechanism: that is, two oxygen atoms in the final product arise from the same oxygen molecule. The mechanism of this unusual process was studied in some detail.⁵⁴ The absolute rate constant for the spontaneous reaction of $(\text{Me}_3\text{Si})_3\text{SiH}$ with molecular oxygen was determined to be $\sim 3.5 \times 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$ at 70°C ⁵⁴ and theoretical studies elucidated the reaction coordinates.⁴⁷ The reaction sequence shown in Scheme 10 corroborates all findings.^{53,54} Silyl radical **31** adds

to oxygen to form the peroxy radical **32**. This silylperoxy radical undergoes three consecutive unimolecular steps: **32** $\rightarrow$ **33** $\rightarrow$ **34** $\rightarrow$ **35**. Hydrogen abstraction from $(\text{Me}_3\text{Si})_3\text{SiH}$ by radical **35** gives the final product **36** and another silyl radical **31**, thus completing the cycle of this chain reaction. There is strong evidence that the formation of the dioxirane-like pentacoordinated silyl radical **33** is the rate-determining step ($\sim 10^3 \text{ s}^{-1}$ at 70°C) of the three consecutive unimolecular steps.

A few aspects of the autoxidation of $(\text{Me}_3\text{Si})_3\text{SiH}$ are of interest to synthetic chemists: (i) in some cases oxygen can serve to initiate radical chain reactions, therefore no additional radical initiator is needed; (ii) the oxidized product **36** does not interfere with radical reactions; and (iii) GC analysis can be used for a titration of the reagent, thus giving the exact concentration of silane if necessary. A highly efficient air-initiated dehalogenation and hydrosilylation reactions with $(\text{TMS})_3\text{SiH}$ as a reducing agent has been established under solvent-free conditions (*vide infra*).^{40,55}

2.1.4 $(\text{TMS})_3\text{SiH}$ /Thiol Pair and Radical Reactions in Aqueous Medium

Earlier work from Roberts' laboratory showed that trialkylsilanes reduce alkyl halides to the corresponding hydrocarbons in the presence of alkanethiols (the so-called polarity-reversal catalysis in the radical chain reduction, see Section 2.2). He demonstrated that the key step in these reductions is the hydrogen transfer from silane to the thiyl radical, which is strongly endothermic and reversible.⁵⁶

Scheme 10 Reaction mechanism for the autoxidation of $(\text{Me}_3\text{Si})_3\text{SiH}$.

On the basis of this approach, the reactivity of $(\text{TMS})_3\text{SiH}$ could be expanded to fast trapping and reducing systems using the $(\text{TMS})_3\text{SiH}$ /thiol pair.⁵⁷ The mechanism in Scheme 11 illustrates the propagation steps with 2-mercaptoethanol as the thiol. Its role is to act as hydrogen donor and then to be regenerated by reaction of thiyl radical with silane. This reactivity can be employed to study the fast reaction of carbon-centered radicals with thiols, using the free-radical clock methodology.⁵⁷ The rate constants of primary alkyl radicals with $(\text{TMS})_3\text{SiH}/\text{RSH}$ and $(\text{TMS})_3\text{SiH}/\text{ArSH}$ are in the range of $0.9\text{--}8 \times 10^7$ and $0.75\text{--}1.5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, respectively, at 80°C (Figure 1). Therefore, the role of thiol is to modulate the hydrogen donor ability of the system and allow the fast reaction

of carbon-centered radicals with the thiols to be studied.

Chemical reactions using water as a solvent have received considerable attention in organic synthesis from both practical and economic standpoints.⁵⁸ The use of water in organic reactions has the following significant advantages: low cost, abundance, safety (nonexplosive, nonflammable, and nontoxic), easily controlled reaction temperature due to the high heat capacity of water, and ease of phase-separation when water-insoluble products are formed. $(\text{TMS})_3\text{SiH}$ is not soluble in water and does not suffer from any significant reaction with water at 100°C for a few hours. This observation motivated our interest in applying it to radical reactions in water (Scheme 12).^{59,60}

Scheme 11 Removal of the X group from alkyl halides using the $(\text{TMS})_3\text{SiH}/\text{RSH}$ reducing system.

Scheme 12 Reduction⁶⁰ and hydrosilylation⁴⁰ reactions in water using (TMS)₃SiH or (TMS)₃SiH/HOCH₂CH₂SH for water-insoluble or water-soluble substrate, respectively.

Water-insoluble substrates, suspended with (TMS)₃SiH and the radical initiator ACCN (1,1'-azobis(cyclohexanecarbonitrile)), in aqueous medium at 100 °C under vigorous stirring can be reduced in good yields.⁶⁰ This procedure does not work with water-soluble substrates; however, when a catalytic amount of the amphiphilic 2-mercaptoethanol is coupled to (TMS)₃SiH, it becomes a very efficient system for the reduction of different organohalides (Scheme 12, upper part). Two examples of water-soluble nucleosides are

shown in Scheme 12, with the dehalogenation of iodide **37** and the reduction of 8-azidoadenosine **38** that afford the corresponding amino derivative **39**. The reduction of aliphatic and aromatic azides to the corresponding primary amines is analogous to that in Scheme 11: that is, after the addition of (TMS)₃Si· radical to the azide moiety, liberation of nitrogen, and formation of a silyl-substituted aminyl radical, the thiol serves as the hydrogen atom donor. Hydrolysis of the silylamine afforded the amine as the final product. Another example

is the hydrosilylation reaction C–C multiple bonds.³⁷ The water-insoluble alkyne **40** afforded the hydrosilylation product in good yield and in *Z/E* ratio of 90:10. Under dioxygen initiation at room temperature, the same reaction product is obtained in similar yield but in *Z/E* > 99 : 1. On the other hand, the water-soluble alkyne **41** afforded in quantitative yield the isomer **42** either under dioxygen initiation at room temperature or with ACCN at 100 °C. These procedures illustrate the flexibility of (TMS)₃SiH as the radical-based reducing agent of choice in different media, as well as additional benefits, including the possibility to work with unprotected substrates, ease of purification, and satisfactory environmental impact.

2.2 Other Organosilanes

Trialkylsilanes are not capable of donating their hydrogen atom at a sufficient rate to propagate the chain. Therefore, chain reactions are not supported under normal reaction conditions, although trialkylsilyl radicals are among the most reactive species toward various organic functional groups. For example, the reduction of thiocarbonyl derivatives by Et₃SiH can be described as a chain process under “forced” reaction conditions.⁶¹ However, Et₃SiH reacts with polyfluorinated halocarbons under free-radical conditions when initiated by thermal decomposition of peroxides.⁶² Phenyl or mixed alkyl/phenyl-substituted silicon hydrides show similar reactivities to trialkylsilanes. Indeed, by replacing one alkyl by a phenyl group, the effect on the hydrogen donating ability of SiH moiety increases only slightly.^{3,7} Although under canonical radical chain conditions these silanes are poor reducing agents, there are some interesting applications, in particular using Ph₂SiH₂.⁶³ The radical-based deoxygenation of bis-xanthate **43** is an example (Scheme 13). A variety of arylsilanes with hydrophilic groups have been prepared for testing radical dehalogenations in aqueous media.⁶⁴ Yields varied from poor to good depending on the substrate and the silicon hydride. The debromination of **44** is an example (Scheme 13). 9,10-Disilaanthracenes as an alternative silane for the reduction of halides and a Barton–McCombie type deoxygenation have also been proposed.^{65,66}

A systematic investigation of organosilanes having different silyl substituents at the SiH

moiety has been carried out with the aim of testing how to tune the reactivity by the choice of substituents. Reductions of a variety of organic derivatives were carried out using RSi(H)Me₂, where R = SiMe₃, SiMe₂SiMe₃, or Si(SiMe₃)₃, and the initiation was provided by benzoyl peroxide or *tert*-butyl perbenzoate (AIBN was found not to be efficient in these cases).⁶⁷ Reduction of a variety of organic derivatives was carried out by using (TMS)₂Si(H)Me under normal reaction conditions, as shown for the reduction of dichloride **45** in Scheme 13.⁶⁸ Although (TMS)₂Si(H)Me does not react spontaneously with oxygen at room temperature, a reaction takes place at 80 °C similar to the one described for (TMS)₃SiH in Scheme 10.⁶⁹ Poly(hydrosilane)s of the type H(RSiH)_nH, where R = *n*-hexyl or phenyl, rival the effectiveness of (TMS)₃SiH in radical chain dehalogenation reactions.⁷⁰ The reduction of iodine **46** is an example. Ph₂Si(H)SiPh₂(H) has been used in the reductions of alkyl bromides, phenyl chalcogenides (e.g., selenide **47**), and xanthates with AIBN in refluxing ethanol or Et₃B/O₂ at room temperature. Yields varied from moderate to excellent, depending on the experimental conditions.⁷¹

Substitution at the SiH moiety has been carried out with alkylthio groups, such as MeS and *i*-PrS. Tris(alkylthio)silanes, (RS)₃SiH, are radical-based reducing agents which can effect the reduction of bromides, iodides, xanthates, phenylselenides, and isocyanides in toluene, using AIBN as the initiator, at 85 °C.⁷²

Silylated cyclohexadienes have been prepared and utilized as radical transfer agents. Silylated 1,4-cyclohexadienes were introduced as reducing agents in radical chain reactions such as dehalogenation, deoxygenation via thionocarbonate ester, and deselenization, as well as hydrosilylating agents for some alkenes and alkynes.^{73–75} Two examples are given in Scheme 14, which show that these reactions also work well with different substituted silyl moieties.⁷⁴ The CH₂ moiety of cyclohexadiene acts as the H-donor with the formation of cyclohexadienyl radical as the intermediate, which rapidly ejects the silyl substrate. Silane-addition products of terminal alkenes are also reported in moderate yields. Two examples are given using the silylated cyclohexadiene **49** (Scheme 14).⁷⁵

The low reactivity of alkyl- and/or phenyl-substituted organosilanes in reduction processes can be ameliorated in the presence of a catalytic

Scheme 13 Removal of functional groups by a variety of silicon hydrides.

amount of alkanethiols. The reaction mechanism is analogous to the one reported in Scheme 11 for $(\text{TMS})_3\text{SiH}$ /thiol pair and shows that alkyl radicals abstract hydrogen from thiols and the resulting thiyl radical abstracts hydrogen from the silane. For this procedure, the term *polarity-reversal catalysis* was coined, which has been applied to dehalogenation, deoxygenation, and desulfurization reactions.^{52,76} For example, 1-bromoadamantane is quantitatively reduced with 2 equiv of triethylsilane in the presence of a catalytic amount of *tert*-dodecanethiol. The reduction of aromatic azides affords anilinosilanes

and hence the corresponding anilines in virtually quantitative yields.⁷⁷ The reaction of thiyl radicals with alkyl-substituted silanes is the key step, being strongly endothermic and reversible. For example, the rate constants k_{SH} and k_{SiH} for the couple triethylsilane/1-adamantanethiol are 3.2×10^4 and $5.2 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, respectively, at 60°C (1). The equilibrium constant $K_{\text{eq}} = k_{\text{SH}}/k_{\text{SiH}}$ is 6.2×10^{-4} and hence ΔG° is $+20.4 \text{ kJ mol}^{-1}$.⁷⁶

Scheme 14 Silylated cyclohexadienes as radical-based reducing agents.

Radical chain hydrosilylation of alkenes has been investigated in some detail.⁷⁵ Poor to moderate yields were obtained for the reaction of Et_3SiH with alkenes at $60\text{ }^\circ\text{C}$.⁷⁸ Thiol catalysis is more effective for the addition of arylsilanes than trialkylsilanes, presumably because the hydrogen abstraction by thiyl radical is more rapid from aromatic silanes.

This methodology has been extended to enantioselective hydrosilylation using optically active thiols as catalysts, such as the thioglucose tetraacetate **50** or the β -mannose thiol **51**.⁷⁹ Scheme 15 shows the hydrosilylation of methylenelactone **52** with various silicon hydrides and thioglucose tetraacetate **50** as the catalyst. Both yields and enantiomeric purities

Scheme 15 Hydrosilylation of C–C double bonds by various silicon hydride/thiol pairs.

increase with the degree of phenyl substitution at silicon. Thiols have also been shown to catalyze the addition of $(\text{TMS})_3\text{SiH}$ to alkenes. Higher enantioselectivities were generally found when β -mannose thiol **51** was used as hydrogen donor. The extra bulkiness provided by the *gem*- β -diphenyl groups in the alkene **53** compared to the alkene **52** is responsible for the high enantiomeric purity observed.

3 SILANES AS MEDIATORS OF CONSECUTIVE RADICAL REACTIONS

3.1 $(\text{TMS})_3\text{SiH}$ as Mediator

Synthetic strategies based on multistep radical reactions have steadily grown in popularity. Silanes, and in particular $(\text{TMS})_3\text{SiH}$, as mediators have contributed substantially to this area, often giving the best results, compared to other reducing reagents, by coupling reactivity with stereoselectivity.^{2,4,6,7} For example, Nicolaou and coworkers found $(\text{TMS})_3\text{SiH}$ to be a superior reagent in the radical-based approach toward the synthesis of azadirachtin, an antifeedant agent used as insecticide, as well as in other related systems.^{80,81}

The carbon-centered radical $\text{R}^\bullet$, resulting from the initial atom (or group) removal by a silyl radical or

by addition of a silyl radical to an unsaturated bond, can be designed to undergo a number of consecutive reactions prior to H-atom transfer. The key step in these consecutive reactions generally involves the intra- or intermolecular addition of $\text{R}^\bullet$ to a multiple-bonded carbon acceptor. As an example, the propagation steps for the reductive alkylation of alkenes by $(\text{TMS})_3\text{SiH}$ are shown in Scheme 16.⁸ This sequence requires a radical reagent that is fast to abstract the group Z from the starting material but not too fast to reduce the corresponding $\text{R}^\bullet$ prior its addition to the multiple bonds. $(\text{TMS})_3\text{SiH}$ characteristics correspond well with these features, since the reagent is a slightly slower hydrogen donor than Bu_3SnH (Figure 1).

3.1.1 Intramolecular Reactions

The majority of sequential radical reactions deal with cyclization as the key step. The constructions of carbocycles, oxygen, and nitrogen heterocycles using $(\text{TMS})_3\text{SiH}$ as a mediator are numerous and represent the importance and expansion of this synthetic approach. Below, we have collected a number of reactions mostly from the recent work in the area of intramolecular reactions.

In the construction of carbocycles, five-membered ring formation has been used for preparing spiro-compounds starting from bromide **54** in

Scheme 16 Reductive alkylation of alkenes by $(\text{TMS})_3\text{SiH}$ ($\text{In}^\bullet$ is the radical derived from the initiator).

excellent yields (Scheme 17).⁸² Bromide **55** is the starting material of six-membered radical cyclization under standard reaction conditions.⁸³ It is worth underlining the complete diastereocontrol in which three contiguous stereocenters are generated in one step with >95% stereoselectivity. For preparing fused cyclic compounds such as functionalized diquinanes, the reaction of selenide **56** with (TMS)₃SiH furnished the expected product in 80% yield and in an $\alpha : \beta$ ratio of 82 : 18, as the result of a kinetic controlled reaction (Scheme 17).⁸⁴

As a strategy for the construction of cyclic ethers, the radical cyclization of β -alkoxyacrylates was used for the preparation of *cis*-2,5-disubstituted THFs and *cis*-2,6-disubstituted tetrahydropyrans. An example is given with β -alkoxymethacrylate **57** as precursor for the cyclization of the optically active benzyl ether of (+)-methyl nonacate, exclusively formed as the threo product (Scheme 18).⁸⁵ Enantioselective radical cyclizations have been performed by using chiral Lewis acids together with (TMS)₃SiH as reducing agent. An example with 70% ee is given, in which the selective coordination of one of the enantiotopic sulfonyl oxygen in ω -iodoalkenyl sulfone **58** is achieved using Zn(OTf)₂-bis(oxazoline)-Ph **59**.⁸⁶ After the

5-*exo*-trig cyclization, the hydrogen atom transfer from silane proceeds with high enantioselectivity to give the cyclic ether in 90% yield. Similar asymmetric reactions were extended to 6-*exo*-trig cyclization as well as to 5-*exo*-trig cyclization of vinyl radicals, with good yields and enantioselectivity.⁸⁶ Another example of Lewis acid complexation that assists the radical cyclization is given by aluminum tris(2,6-diphenyl phenoxide) (ATPH).⁸⁷ The β -iodoether **60** can be complexed by 2 equiv of ATPH, which has a very important template effect, facilitating the subsequent radical intramolecular addition and orienting the (TMS)₃SiH approach from one face in radical **61**. The result is the formation of a cyclization product with *Z* selectivity and in quantitative yield (Scheme 18).

An example of acyl radical cyclization is given for substrate **62** (Scheme 19).⁸⁸ The careful choice of the configuration of the double bond, combined with conformational features of the pre-existing ring in the starting material **62**, can improve the poor diastereoselectivity of 6-*exo*-trig cyclizations. The (iodomethyl)cyclobutane derivative **63** undergoes ring-expansion with (TMS)₃SiH to afford the *cis*-oxepane in excellent yield (96%).⁸⁹ The higher selectivity of (TMS)₃SiH compared

Scheme 17 Construction of carbocycles using (TMS)₃SiH.

Scheme 18 Furan-ring construction using $(\text{TMS})_3\text{SiH}$.

to Group 14 reducing agents was ascribed to the greater steric bulkiness of the silane. The cyclization strategy using $(\text{TMS})_3\text{SiH}$ as mediator has also been carried out for lactone formation. An example of appropriately designed *o*-bromobenzoate ester **64** allowed successful spirocyclization processes and lactone synthesis.⁹⁰ A series of keto spiro- γ -lactones, spirodilactones, spiro lactone-lactams, and spiro lactone-thiolactones have been prepared by this quite general route.^{90,91}

A synthetic strategy for the stereoselective construction of *trans*-2,5-disubstituted cyclic amines has been reported.⁹² The alkyl bromides **65** were prepared with an oxouracil moiety to function as the free-radical acceptor. The reaction with $(\text{TMS})_3\text{SiH}$ and Et_3B in the presence of air at room temperature provided the corresponding azabicycles **66** in high diastereomeric ratio, as the consequence of the stereoselective intramolecular addition of alkyl radical to the oxouracil acceptor, driven by the

rotamer preference (Scheme 20). Similar results have been obtained by replacing the Me group with Ph in the chain. Further treatment of the azabicycles **66** afforded the amino esters **67**, using *p*-methoxyphenol, or the dipeptides **68**, by reaction with BnNH_2 and then $\text{Et}_3\text{N}/\text{PhC}(\text{O})\text{Cl}$. This synthetic strategy has also been adapted to the cyclization of acyl radicals.⁹² A diastereoselective radical route to 2,4-disubstituted piperidines has been achieved in good yields (60–90%) by cyclization of 7-substituted-6-aza-8-bromooct-2-enoates (**69**) using $(\text{TMS})_3\text{SiH}$ as the reducing agent.^{93,94} Four examples are given in Scheme 20, where the *trans/cis* diastereomeric ratios range from 73:27 for $\text{R} = \text{R}' = \text{Me}$ (90% yield) up to $>99:1$ for $\text{R} = s\text{-Bu}$ and $\text{R}' = t\text{-Bu}$ (60% yield). Although the bulkiness of the ester does not appear to have a significant effect on the stereoselectivity, the bulkiness of the 2-substituent increases the pseudo $\text{A}^{1,3}$ strain and favors the *trans* product.

Scheme 19 Construction of cyclic ethers and lactones using $(\text{TMS})_3\text{SiH}$.

Scheme 20 Construction of cyclic amines using $(\text{TMS})_3\text{SiH}$.

Scheme 21 Construction of nitrogen heterocycles using $(\text{TMS})_3\text{SiH}$.

The aryl radical cyclization has been successfully used for the preparation of a variety of indoline derivatives^{95–98} and polycyclic lactams^{99,100} (Scheme 21). Radical cyclization of **70** mediated by $(\text{TMS})_3\text{SiH}$ under standard reaction conditions worked well to afford the cyclic product in 85% yield.⁹⁷ Similar results are obtained for a benzothienopyridine analog.⁹⁶ Another example is shown in the cyclization of **71** mediated by $(\text{TMS})_3\text{SiH}$ and AIBN in refluxing toluene.⁹⁸ Starting from readily available substrates, a new one-pot procedure has been devised to prepare polycyclic lactams and sultams. 2-Pyrroline **72** was obtained from *N,N*-bisallylamide by ring-closure metathesis and subsequent isomerization promoted by ruthenium hydride complexes, and then underwent radical cyclization to furnish tricyclic lactam in good yield

(Scheme 21).⁹⁹ The *N,O*- and *N,S*-heterocyclic fused ring products **74** were also synthesized under radical chain conditions (Scheme 21). Ketene acetals **73** readily underwent stereocontrolled aryl radical cyclization upon treatment with $(\text{TMS})_3\text{SiH}$ under standard reaction conditions to afford the central six-membered ring.¹⁰⁰ The tertiary *N,O*- and *N,S*-radicals formed upon aryl radical reaction at the ketene-*N,X*-acetal double bond ($\text{X} = \text{O}, \text{S}$) appear to have reasonable stability. The stereoselectivity in the hydrogen abstraction step by these intermediate radicals from $(\text{TMS})_3\text{SiH}$ was investigated and found to provide higher selectivities than Bu_3SnH .

$(\text{TMS})_3\text{SiH}$ and AIBN in toluene at 90 °C was used together with an aryl iodide for a

radical-induced transannular ring contraction, which is the key step in the first total synthesis of cavicularin.¹⁰¹ Cyclization of an aryl radical to the adjacent arene further evolved to the target of spirocyclohexadienone, a moiety common to various biologically active compounds.¹⁰² An example is shown in Scheme 22 for the synthesis of spirodihydroquinolone **76**. A solution of the appropriate trityl precursor **75** in benzene (0.15 M) was treated with 1.2 equiv of (TMS)₃SiH and 1.2 equiv of Et₃B, and the resulting mixture was stirred at room temperature open to air until the starting material was consumed (typically 3 hours). The

reactions proceed via ipso cyclization of aryl radicals to oxygen-substituted aromatic ring, followed by β -fragmentation of the trityl substituent to give the desired product (see **Radical Arylations**). The (TMS)₃SiH-mediated cyclization of aryl iodide **77** is facilitated by oxidative rearomatization with oxygen.¹⁰³ Actually, the AIBN is not necessary for the good performance of the reaction, and a mechanistic proposal is given below.

Synthesis of quinolinylum salt **79** was obtained in moderate yields by slow addition of a solution of 2 equiv of both TTMSS and AIBN in *m*-xylene to a solution, at reflux temperature, of pyridinium salt

Scheme 22 Cyclization of an aryl radical to the adjacent arene mediated by (TMS)₃SiH.

78 in dry acetonitrile (Scheme 22).¹⁰⁴ Analogously, the reaction of bromopyridine **80** with TTMSS and azobis(cyclohexanenitrile) (ABCN) in *m*-xylene at 80 °C afforded the 3-aryl-2-aminopyridines **81** through an ipso-substitution of the initially formed aryl radical to the adjacent arene with formation of the carbamoyloxyl radical that affords the aminyl radical by decarboxylation and final reduction by TTMSS.¹⁰⁵

(TMS)₃SiH-mediated radical cyclization has been applied to the formation of ring **C** in two pentacyclic alkaloids (Scheme 23).^{106,107} After condensation of the **AB** and **DE** rings, the appropriate precursors, bromide **82** and seleno ester **84**, were treated with (TMS)₃SiH and AIBN in benzene to give the pentacycles **83** and **85**, respectively. In the reaction of **82**, AIBN was used in catalytic amount,¹⁰⁶ whereas in the reaction of **84** the initiator was in large excess.¹⁰⁷ The reactions are not radical chain reactions, because the radical derived from the decomposition of AIBN involved in some way in the oxidation or rearomatization of the intermediate radical after cyclization.

The (TMS)₃SiH undergoes addition to the carbonyl group of aldehydes and ketones to give the hydrosilylation products.¹⁰⁸ However, synthetically useful addition to carbonyl is limited.^{109–111} The most interesting example is the synthesis of (5′S)-5′,8-*cyclo*-2′-deoxyadenosine, a tandem-type lesion observed among the DNA modifications.¹¹² The reaction of aldehyde **86** with (TMS)₃SiH under typical reaction conditions, that is, 1.2

equiv of reducing agent and catalytic amount of AIBN at 80 °C, showed a low conversion of the starting aldehyde. However, when aldehyde **86** was treated with 5 equiv of (TMS)₃SiH and stoichiometric amount of AIBN at 85 °C under air, it was converted quantitatively in 2 hours to the cyclonucleoside **87** as the sole product in a 75% yield (Scheme 24).¹¹¹ From a mechanistic point of view, the addition of (TMS)₃Si• radical to aldehyde **86** affords the C5′ radical **88** which then attacks intramolecularly the adenine moiety to give **89**. The cyclization occurs with defined stereochemistry, affording exclusively the chair conformation in the forming rings. Oxygen has been suggested to facilitate subsequent rearomatization either directly¹¹³ or via a peroxy radical. It is worth mentioning that it has been reported that (TMS)₃SiCl can be used for the protection of primary and secondary alcohols.¹¹⁴ These (TMS)₃Si-protected alcohols can be deprotected by the usual reaction conditions employed in organic synthesis for the deprotection of other silyl groups. The deprotected alcohols were obtained in 62–95% yields by using photolysis at 254 nm. Indeed, exposure of **87** to UV irradiation for 30 min at room temperature in CH₂Cl₂/CH₃OH (8:3) mixture afforded the 5′-*O*-desilylated compound in 54% yield.¹¹¹ Although a simple hydrosilylation/deprotection combination is formally equivalent to the ionic reduction of carbonyl moieties, the use of an aldehyde functional group in consecutive radical reactions followed by photodeprotection is a new approach for the formation

Scheme 23 Construction of pentacyclic alkaloids using (TMS)₃SiH.

Scheme 24 Reaction mechanism for the synthesis of (5'*S*)-5',8-cyclo-2'-deoxyadenosine.

of new stereogenic centers based on the hindered properties of the (TMS)₃Si-group.

Another interesting example of radical translocation followed by oxidation, where (TMS)₃SiH proved to be the best radical mediator, is illustrated in Scheme 25.¹¹⁵ In particular, the radical-promoted functionalization of the angular carbon was developed with the readily available bromomethylsilyl acetal **90**. A large excess of Cu(OAc)₂ (10 equiv) and AIBN (3 equiv) is required together with (TMS)₃SiH (3 equiv). The electron-rich captodative radical produced after the 1,5-hydrogen atom transfer is readily oxidized by Cu(OAc)₂ to afford the desired acetate **91** in 42% yield, together with the corresponding alcohol in 25% yield. Such a procedure for selective oxidation of the angular methane carbon of hydroxyproline-derivatives should be useful for oxidative elaboration of analogous molecules. On the other hand, when bromide **92** is treated with (TMS)₃SiH and 2 equiv of dilauroyl peroxide (DLP), the spiro-derivative **93** was obtained in one step and 37% yield. The organic peroxide appears to act as the initiator and the oxidant. In this case, the 6-endo cyclization of aryl radical onto an enamide double bond is followed by a consecutive oxidative-ionic spirocyclization at C-3 of an indole nucleus.¹¹⁶

Scheme 25 Examples of unimolecular radical processes followed by oxidation.

A general method of one-carbon ring-expansion of cycloketones was introduced in the late 1980s and proved to be a powerful synthetic tool.^{117,118} (TMS)₃SiH has been used for studying in details the mechanism of ring-expansion of cyclopentanone **94**

Scheme 26 Ring-expansion mediated by $(\text{TMS})_3\text{SiH}$.

Scheme 27 Internal homolytic substitution at sulfur and selenium mediated by $(\text{TMS})_3\text{SiH}$.

Scheme 28 Intermolecular C–C bond formation using TTMS as mediator.

to cyclohexane **95** as shown in Scheme 26.^{118,119} This protocol has been successfully applied to the iodo derivative **96** with the formation of a seven-membered ring in 54% yield.⁸²

A method for the synthesis of cyclic sulinates based on the intramolecular homolytic substitution at sulfur by alkyl radicals was found to be effective.¹²⁰ An example is illustrated for the reaction of di-*tert*-butyl-substituted sulfinate **97** with TTMS and 4,4'-azobis(4-cyanovaleric acid) (V-501) in refluxing toluene which affords exclusively the *trans* isomer in good yield. C–Se and C–Te bonds are formed by an internal homolytic substitution of vinyl or aryl radicals at selenium or tellurium with

the preparation of selenophenes and tellurophenes, respectively (see **Intramolecular Homolytic Substitutions in Synthesis**).¹²¹ Two examples are shown in Scheme 27, where $(\text{TMS})_3\text{SiH}$ was used in the cyclizations of vinyl iodides **98** and aryl iodides **99** that afford (after concomitant dehydration) the selenophene-3-carboxylates and benzene-selenophenes in good yields.^{121,122} The presence of $(\text{TMS})_3\text{SiH}$ after the reductive cyclization to give 3-hydroxylselenophenes induced also the dehydration, presumably through an intermediate silyl ether.

3.1.2 Intermolecular Reactions

Intermolecular C–C bond formation mediated by $(\text{TMS})_3\text{SiH}$, which is illustrated in Scheme 16, has been the subject of several synthetically useful investigations. The effect of the bulky $(\text{TMS})_3\text{SiH}$ can be appreciated in the example shown in Scheme 28. The reaction of α -methylenebutyrolactone **100** with n -BuI affords of α,β -disubstituted lactone in good yield and diastereoselectivity.¹²³ The analogous reaction of lactone or lactam **101** having γ -phenyl with n -BuI gives the corresponding α,γ -disubstituted derivatives also with high *cis* selectivity.^{123,124} The *anti*-rule can be successfully applied for the prediction of stereochemistry: that is, H-donation preferentially occurs in the *anti* fashion to the substituents in the cyclic radical intermediate, in order to reduce steric interference with bulky silicon hydride. Indeed, for the analogous reactions of β - or γ -alkyl substitution were found to be less selective.¹²³ A variety of iodoalkyl derivatives undergo clean free-radical addition to thiomaleic anhydride **102** to give substituted thiosuccinic anhydrides in high yield under standard reaction conditions.¹²⁵

Alkyl radical addition reactions to styrene chromium tricarbonyl **103** can be accomplished

using alkyl halides (10 equiv) and TTMSS (5 equiv) in the presence of AIBN in refluxing benzene.¹²⁶ As an example, the addition of cyclohexyl radical is given in Scheme 29. These reactions are believed to proceed through intermediates in which the unpaired electron is interacting with the adjacent arene chromium tricarbonyl moiety since the analogous reaction with styrene affords only traces of addition products. Another interesting case of C–C bond formation is the radical reaction at the anomeric center of carbohydrates with vinylphosphonate derivatives.^{127,128} Indeed, the highly stereoselective preparation of α -substituted C-glycosyl phosphonates in an $\alpha:\beta$ ratio of 98:2 was achieved by reductive addition of bromide **104** to α -phosphonoacrylate. Yields (in parenthesis) depend on the sugar configuration: D-galacto (80%), D-manno (47%), D-glucos (30%), and L-fuco (62%).¹²⁸ The use of $(\text{TMS})_3\text{SiH}$ with acyl selenides can also yield new C–C bond formation with the α,β -unsaturated lactam ester **105**. The resulting ketone **106** can be envisaged as potentially useful for the synthesis of 2-acylindole alkaloids.¹²⁹ The combined effects of H-donating ability and steric hindrance by the silicon hydride are evident in the stereochemical outcome.

Schemes 30 and 31 show two classes of intermolecular C–C bond formation carried out

Scheme 29 Intermolecular C–C bond formation using TTMSS as mediator.

Scheme 30 Enantioselective radical reactions using TTMSS as mediator.

by Lewis acid-mediated enantioselective radical reactions.^{130,131} Conjugated radical additions to a variety of α,β -unsaturated imides **107** were performed at room temperature using 3 equiv of the hydrogen donor TTMSS and $\text{Et}_3\text{B}/\text{O}_2$ as initiator in CH_2Cl_2 .¹³⁰ The chiral Lewis acid derivative from magnesium triflimide and bisoxazoline **108** was used. Modest enantioselectivities of 20% and 51% were obtained for oxazolidinone-derived and pyrazolidinone-derived crotonate, respectively. However, substituted imides were found to give the best yields and enantioselectivities. Phenyl, 4-Cl-phenyl, and *tert*-butyl imide substituents provided enantioselectivity enhancement, the last one giving 83%. On the other hand, binaphthol-derived chiral phosphoric acid catalysts were applied to radical addition reactions of imines, which provided chiral amines in good yields and good enantioselectivities.¹³¹ Three examples are shown in Scheme 31. The highest enantiomeric excess was obtained for the addition of ethyl radical to imine **109** using the

catalyst **110** in THF at -40°C . The enantioselectivities were not affected by the electronic properties of imines.

Intermolecular formation of C–C bond can also be coupled with β -elimination process. In this case, the reaction partners are designed to generate the alkyl radicals $\text{R}^\bullet$, which gives the addition to unsaturated bonds. The radical adducts obtained so far do not terminate by H donation from $(\text{TMS})_3\text{SiH}$, but give the β -elimination process with loss of radical $\text{X}^\bullet$ that abstracts hydrogen from silicon hydride in order to complete the radical chain. This strategy can be successfully carried out by the proper choice of the X group (that can give a stabilized radical species) and the hydrogen donor. Examples are given in Scheme 32, which formally represent an allylation and a cyanation protocol, respectively. Radical allylation with $(\text{TMS})_3\text{SiH}$ as the mediator and 2-functionalized allyl phenyl sulfones **111** occurred with moderate to good yields, depending on the nature of the starting materials.¹³² The reaction

Scheme 31 Enantioselective radical reactions using TTMSS as mediator.

Scheme 32 Allylation and cyanation protocols mediated by TTMSS.

proceeds via addition of the adamantyl radical to the double bond, giving rise to an intermediate that undergoes β -scission to form $\text{PhSO}_2^\bullet$ radical, which abstracts hydrogen from the silane to regenerate $(\text{TMS})_3\text{Si}^\bullet$ radical. The glycosyl radical cyanation yielded α -cyanoglycosides **112** in variable yields, depending on the configuration of sugar: D-galacto (73%), D-manno (40%), D-gluco (71%), and L-fuco (25%). Only α -cyano anomers were formed.¹³³ The key propagation steps for these transformations are the addition of glycosyl radical to the carbon atom of the isocyanide moiety, followed by a fragmentation yielding a *tert*-butyl radical and the desired glycosyl cyanide. *tert*-Butyl radical abstracts hydrogen from the silane to complete the chain.

The $(\text{TMS})_3\text{SiH}$ -mediated addition of fluoroalkyl radicals to alkenes have also been reported.^{134,135} The addition of perfluoroalkyl iodides or bromides to a variety of alkenes afforded the expected adducts

113 with moderate to good yields in water as the solvent (Scheme 33).¹³⁴ Two versatile and convenient methodologies were individuated depending on the nature of the starting materials: that is, with iodides the initiation step with molecular oxygen was sufficient to ensure smooth reaction at room temperature, whereas with bromides the azo-initiation at 70 °C was necessary. Phenylseleno derivatives **114** are found to be good precursors of phosphonodifluoromethyl and phosphonothiodifluoromethyl radicals under normal reaction conditions: that is, refluxing toluene and AIBN as initiator (Scheme 33). Moreover, when generated by the $(\text{TMS})_3\text{Si}^\bullet$ attack on **114** and in the presence of alkenes or alkynes, they gave access to α,α -difluorinated derivatives **115** and β,γ -unsaturated adducts **116**, via carbon–carbon bond formation. The phosphonothio derivatives are obtained in higher yields than phosphonates in both reactions.¹³⁵

Scheme 33 Fluoroalkyl radicals addition to C–C multiple bonds mediated by TTMSS.

Homolytic aromatic substitution often requires high temperatures, high concentrations of initiator and long reaction times, and typically occurs in moderate yields (see **Radical Arylations**).¹³⁶ Such reactions are often conducted under reducing conditions with $(\text{TMS})_3\text{SiH}$, even though the reactions are not reductions and often finish with oxidative rearomatization. The reaction of 2-bromopyridine with pyridine is an example where a solution containing silane (2 equiv) and AIBN (2 equiv) is slowly added over 8 hours (Scheme 34).¹³⁷ The synthesis of 2,3'-bipyridine **118** presumably occurs via the formation of the cyclohexadienyl radical **117** and its rearomatization by disproportionation with the alkyl radical derived from AIBN.¹³⁶ Heteroaromatic bases activated by protonation with trifluoroacetic acid react with alkyl bromides or iodides and $(\text{TMS})_3\text{SiH}$ under thermal conditions (in the presence of 1–2 equiv of AIBN in benzene), affording the desired product in moderate to good yields.¹³⁸ An example is the reaction of protonated lepidine with cyclohexyl radical to give **119** in 94% yield (Scheme 34). Here again, the stoichiometric quantity of AIBN ensured the rearomatization of the stabilized cyclohexadienyl-type radical intermediate, which reaches a stationary concentration

suitable for intercepting the α -cyanoisopropyl radical, thus leading to the substitution product. Similar examples are the $(\text{TMS})_3\text{SiH}$ -mediated addition of aryl iodides to benzene, which are facilitated by oxidative rearomatization of **120** with oxygen.¹⁰² Here, AIBN is not necessary for good performance of the reaction. The reaction proceeds well in both inter- and intramolecular (*vide supra*) versions.

An interesting methodology for the synthesis of *N*-alkoxylamines mediated by $(\text{TMS})_3\text{SiH}$ has also been developed.¹³⁹ The method consists of the trapping of alkyl radicals generated *in situ* by stable nitroxide radicals. To accomplish this simple reaction sequence, an alkyl bromide or iodide was treated with $(\text{TMS})_3\text{SiH}$ in the presence of thermally generated *t*-BuO $\cdot$ radicals. The reaction is not a radical chain process and stoichiometric quantities of the radical initiator are required. This method allows the generation of a variety of carbon-centered radicals such as primary, secondary, tertiary, benzylic, allylic, and α -carbonyl, which can be trapped with various nitroxides. Examples of the intermolecular phosphorous–carbon bond formation are numerous. The $(\text{TMS})_3\text{SiH}$ -mediated addition of phosphorus-centered radicals to a number of alkenes

Scheme 34 Homolytic aromatic substitution mediated by TTMSS.

has been investigated in some detail.¹⁴⁰ The synthesis of **121** is an example using four structurally different phenylseleno derivatives with 3 equiv of (TMS)₃SiH and AIBN in refluxing benzene for 2 hours (Scheme 35). Comparative studies on the reaction of the four phosphorus-centered radicals have been obtained. Although the reaction with 1-methylene cyclohexane is efficient with all four derivatives, different selectivities are observed with electron-rich or electron-poor alkenes.¹⁴⁰ Intermolecular C–P bond formation by means of radical phosphonation¹⁴¹ and phosphination¹⁴² has been achieved by reaction of aryl halides with trialkyl phosphites and chlorodiphenylphosphine, respectively, in the presence of (TMS)₃SiH under standard radical conditions (Scheme 35). The phosphonation product **122** was obtained either under UV irradiation at room temperature or in refluxing toluene. The phosphination procedure of iodides **123**, which involves *in situ* formation of tetraphenylbiphosphine from Ph₂PCl, required pyridine in boiling benzene for 20 hours. Phosphinated products were handled as phosphine sulfides **124**. This approach was extended to the phosphination of alkyl halides and sequential radical cyclization/phosphination reaction.¹⁴²

3.1.3 Tandem and Cascade Reactions

The increasing popularity of radical reactions is certainly due to the so-called tandem or cascade reaction: that is, the ability of forming and breaking several bonds in a one-pot procedure (see **Radical Cascade Reactions**). Carbonylation procedures have been successfully used for radical strategies of C–C bond formation. Alkyl halides were carbonylated under moderate pressure of CO in benzene at 80 °C in the presence of (TMS)₃SiH and AIBN.^{22,143} An example of carbonylation of a primary alkyl bromide is shown in Scheme 36. This radical chain reaction proceeds by the addition of the alkyl radical onto carbon monoxide, which generates an acyl radical intermediate **125**, which, in turn, abstracts hydrogen from the silane to give the corresponding aldehyde. Examples of three-component coupling reactions are also given in Scheme 36. The cascade proceeds by the addition of an alkyl or a vinyl radical onto carbon monoxide with formation of an acyl radical intermediate, which can further react with electron-deficient olefins to lead to the polyfunctionalized compounds **126** and **127**, respectively.^{22,143}

Supercritical carbon dioxide (scCO₂) is an emerging reaction medium for free-radical reactions for

Scheme 35 Intermolecular C–P bond formation using TTMS as mediator.

a number of reasons, such as the pressure-tunable cage effect, the absence of radical chain transfer to the medium,¹⁴⁴ and unique properties such as high diffusivity and high miscibility of the reactant gases.¹⁴⁵ Since $(\text{TMS})_3\text{SiH}$ does not react with CO_2 and CO is highly soluble in scCO_2 , it is thought that radical carbonylation in scCO_2 should be characterized by high tenability of product distribution.¹⁴⁶ Indeed, the extension of the three-component coupling reaction in this reaction medium gave excellent results, as shown in Scheme 36 for the reaction of alkyl iodide with a variety of alkenes to give **128** in excellent yields.

The addition of $(\text{TMS})_3\text{SiH}$ to the substituted 1,5-dienes in the presence of CO is an intramolecular version of the above-mentioned strategy and represents an example of $(4 + 1)$ radical annulation process to give the cyclic ketone

129 (Scheme 37).¹⁴⁷ Indeed, the initial addition of silyl radicals to the least substituted terminus is followed by carbonylation and acyl radical cyclization prior to hydrogen abstraction. This methodology has been further developed for the preparation of cyclic ethers. An example is given for compound **130**, derived from the easy regioselective ring-opening of appropriate epoxides with benzeneselenoate followed by hetero-Michael addition to ethyl propiolate, which underwent radical tandem carbonylation/cyclization reaction in the presence of $(\text{TMS})_3\text{SiH}$ and CO (80 atm) to give **131**.¹⁴⁸

Barton–McCombie deoxygenation of 7-azabenzonorbornanols via xanthate derivatives such as **132** afforded the corresponding 2-azabenzonorbornanes in 64–90% yields.^{149–152} These compounds are not

Scheme 36 Three-component coupling reactions mediated by TTMSS.

Scheme 37 Tandem reactions mediated by TTMSS for the construction of cyclic ketones.

readily accessible by other means. The reaction proceeds through the neophyl-type radical rearrangement **134** $\rightarrow$ **135** with a rate constant of $\sim 10^5\text{ s}^{-1}$ at 111°C (Scheme 38).¹⁵⁰ It was also found that the slow addition of silane in the presence of

methyl acrylate (or other electron-deficient alkenes) gave good yields of the rearranged trapped azacycle **133**. Extension of these processes to provide enantio-enriched products was successfully applied after desymmetrization of the starting materials.¹⁵¹

Scheme 38 Synthesis of 2-azabenzonorbornanes via neophyl-type rearrangement.

Substituted 5',8-cyclopurine and 5',6-cyclopurimidine nucleosides have been synthesized by combining radical translocation/cyclization steps.^{153,154} Two examples are shown in Scheme 39. Treatment of the 8-bromo derivative **136** or 6-phenylseleno derivative **138** with $(\text{TMS})_3\text{SiH}$ and AIBN in benzene at 80 °C for 4 hours resulted in the cyclonucleosides **137** and **139**, respectively. The initially generated radical on the base moiety by Br or PhSe abstraction translocates to C5' position of sugar by

hydrogen atom transfer followed by cyclization on the base moieties (cf. Scheme 14). Rearomatization or hydrogen abstractions complete the cycle, affording the cyclonucleosides in good yields and diastereomeric ratio in favor of the (5'S) isomer.

Radical-based tandem cyclizations favor the application of TTMSS over other reducing agents, owing to the absence of toxicity and high chemoselectivity. A nice example of two consecutive 5-exo cyclizations in a one-pot reaction is illustrated

Scheme 39 Synthesis of cyclonucleosides mediated by TTMSS.

Scheme 40 Two consecutive reductive cyclizations mediated by TTMSS.

Scheme 41 Tandem cyclizations mediated by TTMSS (the new C–C bonds are shown in red).

in Scheme 40. Starting from dibromide **140**, the first cyclization via the radical **142** affords the desymmetrization of the molecule, whereas the second cyclization provides the bicyclic core **141**, which is common to the guttiferone family of natural products.¹⁵⁵ Bridged spirolactones **144** have

been synthesized via tandem radical cyclizations of enol ether **143**, where the first 5-exo spirocyclization is followed by a 6-endo cyclization to give the bridged derivative as a single diastereoisomer (Scheme 41).¹⁵⁶ Free-radical reaction of vinyl iodides having dienolate function in the presence of $(\text{TMS})_3\text{SiH}$ and AIBN in refluxing benzene caused tandem cyclization reactions to produce (4 + 1) and (4 + 2) annulated compounds.¹⁵⁷ The transformation **145** → **146** resulted from a tandem 5-exo, 6-endo cyclization to give the isoindole skeleton where the stereogenic centers are highly controlled. Reactions that feature a 7-exo acyl radical cyclization followed by a 6-exo or 5-exo alkyl radical cyclization proceed with very good yields and diastereoselectivities.¹⁵⁸ As an example, the treatment of **147** with $(\text{TMS})_3\text{SiH}$ at room temperature provided the tricycles **148** in excellent yields as a single diastereomer. Interestingly, the bulky silyl ether moiety is not required to achieve stereoselectivity in this process.

Tandem strategies have been successfully applied to the synthesis of alkaloids starting from aryl

Scheme 42 Tandem cyclizations mediated by TTMSS (the new C–C bonds are shown in red).

radical generation. The plan for tandem cyclization as the key step in the synthesis of morphine alkaloids has been successfully implemented.¹⁵⁹ For example, the initially formed aryl radical, generated by bromine abstraction from compound **149**, underwent a tandem cyclization to construct the desired carbocyclic skeleton followed by elimination of thiyl radical and formation of **150** (Scheme 42). The reaction of iodoarylazide **151** with $(\text{TMS})_3\text{SiH}$ under standard experimental conditions and after washing with dilute acid afforded the amine **152** in an overall 83% yield.¹⁶⁰ The skeletons of a variety of alkaloids such as $(\pm)$ -horsfiline, $(\pm)$ -aspidospermidine, and $(\pm)$ -vindoline have been achieved by this route.^{160–162} Radical cyclizations of tetrahydropyridine scaffolds have been used to access diverse skeletal frameworks.¹⁶³ Treatment of the allylated tetrahydropyridine **153** with $(\text{TMS})_3\text{SiH}$ and AIBN in refluxing benzene resulted in a single diastereomer **154** in a 65% isolated yield (Scheme 42).

As model studies and radical reactivity control have improved, the so-called cascade (or domino) reactions have emerged as a very powerful method for natural product synthesis, since it offers a unique route to the preparation of complex backbones from appropriately designed but quite simple precursors. A few selected reactions are presented here. Treatment of the iodo derivative **155** with $(\text{TMS})_3\text{SiH}$ starts a cascade of 6-endo, 6-endo, and 6-exo cyclizations to afford exclusively **156** in 77% yield (Scheme 43).¹⁶⁴ An analogous cascade involving 5-exo, 5-exo, and 5-exo modes of cyclization afforded a linear fused five-membered carbocycle.¹⁶⁵ Radical cascade starting from bromomethyldimethylsilyl propargyl ethers has been utilized in a remarkable way.^{166–168} Reduction of the bromide **157** in the presence of $(\text{TMS})_3\text{SiH}$ and subsequent treatment with MeLi produced the functionalized cyclopentanone precursor **158** as a single diastereomer (Scheme 43). The formation of **158** has been explained by a series of reactions, involving a

Scheme 43 Domino reactions mediated by TTMSS (the new C–C bonds are shown in red).

5-exo cyclization of the initial α -silyl alkyl radical, followed by a [1,5]-radical translocation of the generated σ -type vinyl radical onto the proximal acetal function, and a final 5-exo cyclization process. Stereoselective hydrogen abstraction, dependent on the steric bulkiness of the hydrogen donor, followed by MeLi-induced opening of the Si–O bond, afforded the final product. The introduction of different substituents on the skeleton resulted in a completely different reaction pattern.^{167,168} A radical carboxyarylation approach is also introduced as the key step in the total synthesis of several biologically important natural products.^{169,170} Treatment of thiocarbonate derivatives **159** (R = Me or TBS) with 1.1 equiv of (TMS)₃SiH in refluxing benzene and in the presence of AIBN (0.4 equiv added over 6 hours) as radical initiator, produced compound **160** in 44% yield. This remarkable transformation resulted from a radical cascade, involving (TMS)₃Si $\cdot$ radical addition to a thiocarbonyl function and 5-exo cyclization and intramolecular 1,5-*ipso* substitution, with the final ejection of (TMS)₃SiS $\cdot$ radical.

The number of consecutive reactions in some radical cascade processes can be really astonishing.^{171,172} Three representative examples

are illustrated in Scheme 44. Treatment of the acetylene derivative **161** with (TMS)₃SiH leads, in one pot, to the bicyclic compound **163** in 70% yield. The proposed mechanism involves (TMS)₃Si $\cdot$ radical addition to the triple bond to form a vinyl radical **162**, followed by a remarkable cascade of radical 6-exo cyclization, ring-opening, transannulation, ring-expansion, and termination via ejection of the (TMS)₃Si $\cdot$ radical, to afford the bicyclic product **163**. When a solution of vinyl bromide **164** was irradiated with a sunlamp in the presence of (TMS)₃SiH, it gave the corresponding triquinane oxime **165** as a 1:1 mixture of α - and β -methyl diastereomers resulting from a cascade of radical 6-exo cyclization, aminyl radical fragmentation, 5-exo radical transannulation, and 5-exo cyclization sequence. Treatment of the butenyl-substituted allenecyclopropane **166** with (TMS)₃SiH/AIBN resulted in facile radical cyclizations into the cyclopropane–carbon centers of the allene moieties, followed by cyclopropane ring-opening and allene isomerization, leading to the bicyclic 1,3-diene **167**.¹⁷³ Desilylation of **167** with TBAF in THF gave the corresponding bicyclic 5,6-ring-fused 1,3-diene in 71% yield.

Scheme 44 Radical cascade processes mediated by TTMSS.

3.2 Other Organosilanes

The use of silanes other than $(\text{TMS})_3\text{SiH}$ in sequential reactions has been limited. A few selected examples are shown in Scheme 45. Taking advantage of the high reactivity of alkoxy radicals toward organosilanes, which is 2–3 orders of magnitude higher than that of primary alkyl radicals, cyclization can start from halocarbonyl compounds **168** using PhSiH_3 .¹⁷⁴ Both 6-*exo*-trig and 5-*exo*-trig cyclizations of alkyl radicals to the carbonyl moieties can be accomplished, with aldehydes working better than ketones. The thermally unstable propargyl bromide cobalt complex **169** afforded the cyclization product using Ph_2SiH_2 as reducing agent and $\text{Et}_3\text{B}/\text{O}_2$ as the radical initiator at room temperature.¹⁷⁵ However, a mixture of reduced and bromine atom-transfer products (1:1.8 ratio) was also isolated owing to the low hydrogen-donating ability of

the employed silane. Fused cyclic ethers have been derived from appropriately substituted sugars using 1,1,2,2-tetraphenyldisilane.¹⁷⁶ An example is given with the stereoselective 5-*exo* radical cyclization of allylic 2-bromo-2-deoxysugar **170**, in the presence of silane and AIBN in refluxing ethyl acetate (Scheme 45).

A few examples of the hydrosilylation/cyclization of dienes are given by using the silylated cyclohexadienes **172** as reagents (Scheme 45). The cyclization of 1,6-diene **171** shows how flexible this methodology is to introduce any type of silyl group in the reaction products.¹⁷⁷ Yields are moderate to good, and the *cis*:*trans* ratio of ~4:1 does not change substantially by the nature of the silylating group, as expected.

Procedures for the transformation of thiocarbonates **173** and thiocarbamates **177**, available in a single high-yielding step from phenols, into esters **174** and amides **178** of benzoic acid mediated by Et_3SiH

Scheme 45 Intramolecular C–C bond formation mediated by a variety of silanes.

Scheme 46 Transformation of phenol derivatives into esters and amides of benzoic acid mediated by Et_3SiH .

have also been discovered (Scheme 46).^{178–180} The initiation step is the thermal generation of the *tert*-butoxyl radical from the decomposition of di-*tert*-butyl peroxide (BOOB) or 2,2-bis(*tert*-butyl peroxy)butane (DTBPB), which reacts with Et_3SiH . The $\text{Et}_3\text{Si}^\bullet$ radical adds at the sulfur atom of the $\text{C}=\text{S}$ moiety in analogy to the first step of the Barton–McCombie reaction, producing the carbon radical **175** in the case of thiocarbonates, which undergoes 1,2 $\text{O} \rightarrow \text{C}$ transposition through an *O*-neophyl rearrangement to give alkoxy radical **176**. This metal-free preparation of benzoic acid derivatives from phenols provides a potentially useful alternative to metal-catalyzed carbonylation of aryl triflates.¹⁸⁰

Scheme 47 shows the use of hexyl SiH_3 as reducing agent in the intermolecular C–C bond formation, which is analogous to Scheme 30 reported for TTMSS. In particular, the reactions carried in the presence of chiral Lewis acid derivative from magnesium triflimide and bisoxazoline **108** were used.¹²⁹ The enantioselectivities and yields are similar to those reported for TTMSS. Substituted imides

of **107** were found to give the best yields and enantioselectivities, and the study of *tert*-butyl imide substituent has been extended, providing enantioselectivity up to 94%.

4 CONCLUSIONS

The synthetic application of silyl radical reactivity in the last decade has expanded considerably. $(\text{TMS})_3\text{SiH}$ has become popular among organic chemists and its arrival on the scene has resulted in a great advancement for radical chemistry. Unique transformations are possible, allowing one to generate structures that would otherwise be very difficult to synthesize. The scope and breadth of $(\text{TMS})_3\text{SiH}$'s utility as a mediator of consecutive radical reactions is spectacular, and we are convinced that much more diverse applications are yet to come. The need for nontoxic reagents such as $(\text{TMS})_3\text{SiH}$ to achieve these steps is evident, since chemical and biological issues are satisfied simultaneously. It seems pertinent to suggest a significant role of $(\text{TMS})_3\text{SiH}$ or the $(\text{TMS})_3\text{SiH}$ /thiol couple in

Scheme 47 Enantioselective radical reactions using hexylSiH₃ as mediator.

aqueous or heterogeneous media in future research. We trust that this article will serve as a platform to expand silicon radical chemistry with new and exciting discoveries.

Unusual Radical Acceptors

Piero Spagnolo and Daniele Nanni

Dipartimento di Chimica Organica "A. Mangini", Università di Bologna, Bologna, Italy

1 INTRODUCTION

When chemists think about radical reactions, and in particular about applications of radical reactions to organic synthesis, the mind of even the more acquainted ones runs immediately to additions to carbon–carbon multiple (mostly double) bonds: maybe also to aromatic compounds (see **Radical Arylations**), one of the first types of radical traps ever studied. People more experienced with radical chemistry are definitely familiar with addition to other moieties such as carbon–heteroatom multiple bonds and the consequent generation of heteroatom-centered radicals (see **Main-Group Elements in Radical Chemistry**). Nevertheless, there are plenty of other unusual traps that are becoming more and more important in the field of radical chemistry, but these are often not taken into consideration by synthetic organic chemists due to either the opinion that they are unstable, not easy to make and sometimes hazardous, or even the unawareness of their ability to act as selective radical acceptors. Among the assortment of uncommon moieties, in this article we will deal with three particular classes of radical acceptors, namely, azides, isonitriles, and heterocumulenes. The choice was primarily dictated by the outstanding results obtained with those acceptors in the domain of radical addition. Moreover, those traps are among the ones that suffer to the maximum extent from instability and/or hazard prejudices. Quite the opposite, we will show that their respective radical adducts are easily accessible and actually give rise to a mine

of stunning synthetic applications that are probably far from being exhausted.

2 AZIDES

2.1 Introduction

Organic azides are long known as extraordinarily useful intermediates for the construction of cyclic and acyclic nitrogen compounds owing to their ability to give rise to a large number of important reactions basically enabled by the 1,3-dipolar nature of the azido group and the inherent aptitude of this functional group for elimination of molecular nitrogen under thermal and photochemical conditions.^{1–4} In spite of the often irrational fear of organic azides caused by their potential explosive features, over the years interest in these nitrogen compounds has continued to increase tremendously owing to a plethora of novel applications.⁴ Since the 1980s, additional interest in their radical reactivity has been revealing that organic azides form a very special family of radical acceptors. Aliphatic and aromatic azides undergo efficient intra- and intermolecular additions of carbon- and heteroatom-centered radicals, leading to ultimate aminyl radicals which are involved in numerous synthetic processes often yielding aza-heterocycles through carbon–nitrogen bond formation. Electron-poor sulfonyl azides readily accept nucleophilic radical species, leading to azido group transfer products by release of a sulfonyl radical. As a result, sulfonyl azides find excellent use as azido

group transfer reagents in homolytic azidation processes. A review appeared in 2009 has exhaustively surveyed the radical chemistry of aliphatic and aromatic azides up to 2008.⁵ In that review, sulfonyl azides were additionally surveyed, but less thoroughly, since their distinctive radical chemistry had already been covered in an earlier comprehensive monograph.⁶ In this article, we shall deal particularly with those mechanistic and synthetic studies that allow more significant insights into the fascinating radical world of the azide family, including not only organic but also inorganic members.

2.2 Organic Azides

2.2.1 Aliphatic and Aromatic Azides as Acceptors of Carbon Radicals

The first documented example of radical addition to an azide dates back to 1978, when we discovered that 2'-azido-2-biphenyl radicals, available from the corresponding diazonium salt by reduction with iodide ion in acetone at 0 °C, gave rise to significant amounts of carbazole products clearly ascribable to carbazolyl radicals arising from cyclization (i.e., intramolecular addition) onto the azido group, accompanied by elimination of molecular nitrogen (Scheme 1).⁷

In spite of that promising chemical information, soon substantiated by Robert's electron paramagnetic resonance (EPR) spectral data,^{8,9} the radical chemistry of azides remained essentially ignored up to the 1990s, when the appearance of further pioneering works stimulated a deep theoretical and

Scheme 1 Cyclization of aryl radical onto an aromatic azide.

Scheme 2 Aminyl radicals from homolytic addition to aliphatic and aromatic azides.

synthetic interest in radical azide reactions, which has virtually seen no interruption. Overall spectral and chemical evidence provided by the reported studies clearly suggests that the azido function of an aliphatic or aromatic azide can undergo homolytic attack at both/either the R-substituted and/or the terminal nitrogen, giving rise to a 3,3-triazenyl (1) and/or a 1,3-triazenyl radical (2), respectively, depending on the structural/polar features of both the attacking radical and the azide substrate (Scheme 2). It is sometimes not clear to which end of the azido moiety addition occurs, because ultimate aminyl radicals could plausibly arise from either triazenyl radical adduct by extrusion of molecular nitrogen.^{8–10}

Aliphatic and aromatic azides are rather modest acceptors of carbon radicals: as a consequence, their *intermolecular* reactions with carbon radicals are of no practical interest. However, the *intramolecular* reactions with typical carbon radicals such as alkyl, vinyl, aryl, carbonyl, and dithiocarbonyl usefully lead to six- and/or five-membered cyclic aminyl radicals that are crucial intermediates in the radical production of a variety of interesting azaheterocycles.

A few years after our original discovery of aryl radicals (Scheme 1), dithiocarbonyl radicals furnished additional instances of intramolecular carbon radical addition to an aromatic azido function.¹¹ Azidodithiocarbonyl radicals **3** and **5** were produced in acetone at 0 °C by the addition of the respective azidoaryl radicals to carbon disulfide. Under these conditions, the dithiocarbonyl **3** gave mercaptothiazole **4**, though to a modest extent, through five-membered cyclization onto the adjacent azide (Scheme 3a), whereas the dithiocarbonyl **5** afforded mercaptotiazine **6** in a notably better yield by a corresponding six-membered cyclization process (Scheme 3b).¹¹

Scheme 3 Cyclizations of dithiocarbonyl radicals onto aromatic azides.

Kim *et al.* subsequently demonstrated that the intramolecular reaction of aliphatic azides with alkyl radicals offers a powerful synthetic access to *N*-heterocycles through the intermediacy of cyclic aminyl radicals.¹² Indeed, various aliphatic azido-iodides and azido-thionocarbonates reacted with tris(trimethylsilyl)silane [(TMS)₃SiH]/AIBN (see **Silanes as Reducing Reagents in Radical Chemistry**) in refluxing benzene giving rise to

good to very good yields of simple/fused pyrrolidines and piperidines via five- and six-membered cyclizations of derived alkyl radicals onto the internal azido substituent (Scheme 4a).¹² In those azide cyclizations, suitable adoption of (TMS)₃SiH reagent was dictated by the original observation that, with iodide and thionocarbonate moieties, the tris(trimethylsilyl)silyl radical strictly forms the alkyl radical even in the presence of an azido substituent. Similarly effective azide cyclizations to pyrrolines and tetrahydropyridines occurred with α -silyloxyalkyl radicals arising from the addition of the oxyphilic tris(trimethylsilyl)silyl radical to the carbonyl groups of azidoketones and azidoaldehydes (Scheme 4b).¹² The fair intramolecular reactivity of alkyl azide with alkyl radical has been next exploited in the synthesis of several important natural products, such as the elegant Murphy's synthesis of Horsfiline (Scheme 4c).^{13–16}

A later work disclosed that aromatic azides can also exhibit easy intramolecular addition of vinyl radicals.¹⁷ Upon reaction with benzenethiol (PhSH)/AIBN in refluxing benzene, azidoacetylene **7** gave a high yield of cyclized indole **9** only, which was clearly due to five-membered cyclization of the derived (benzenesulfanyl)vinyl radical **8a** onto the aromatic azido group. The exclusive occurrence of

Scheme 4 Cyclizations of alkyl radicals onto aliphatic azides.

Scheme 5 Cyclizations of vinyl radicals onto aromatic azides.

indole **9** plausibly arose from fast cyclization of vinyl radical **8a** as well as by reversible production of the regioisomeric vinyl radical **8b**: both factors would explain the absence of any possible vinyl sulfide adduct **10** (Scheme 5, route a).¹⁷ The corresponding reaction with benzylthiol similarly gave the indole analog, but in a moderate yield. The more reactive benzylsulfanyl radical could undergo nearly irreversible addition to the acetylene **7**, thereby leading to the concomitant formation of vinyl benzyl sulfide adduct to a fairly comparable extent (Scheme 5, route b).¹⁷

Aliphatic azides have been last found to form cyclic amidyl radicals upon intramolecular five- and six-membered addition of acyl radicals.^{18,19} Aryl-derived azidoacyl radicals **11a,b** arising from reaction of 2-(*o*-iodophenyl)thiol esters with Bu₃SnH/AIBN and/or (TMS)₃SiH/AIBN actually furnish excellent yields of five- and six-membered lactams **13a,b** via H transfer to the corresponding amidyl radicals **12a,b** (Scheme 6). When

allyltriphenylstannane is used as tin radical precursor, the azidoacyl radical interestingly affords a satisfactory yield of the *N*-allylated lactam by allyl transfer reaction of the cyclized amidyl radical with the allylstannane.¹⁸

Scheme 6 Cyclizations of acyl radicals onto aliphatic azides.

Analogous cyclizations to lactams are somewhat less feasible with alkyl-derived azidoacyl radicals, owing to the fair tendency of alkanoyl radicals to undergo decarbonylation.¹⁸

2.2.2 Aliphatic and Aromatic Azides as Acceptors of Heteroatom-Centered Radicals

Alkyl and aryl azides are notably better radical acceptors of tin than carbon radicals. Indeed, the intermolecular reactions of these azides with tributyltin radicals smoothly lead to *N*-(tributylstannyl)aminyl radicals, which actually are the key intermediates in numerous very useful azide processes mediated by Bu₃SnH/AIBN. Tin-bound aminyl radicals are a more appealing species than “ordinary” aminyl analogs since, besides being easily accessible, they display increased nucleophilic character and hence, often, increased reactivity.^{20–22} Computational studies reported by Kim *et al.* actually show that the *N*-(trimethyltin)-substituted methylaminyl radical has higher singly occupied molecular orbital (SOMO) energy, as well as higher electron density at nitrogen, than the dimethylaminyl and methylaminyl counterparts.²² Aromatic and aliphatic azides react with Bu₃SnH/AIBN, typically in refluxing benzene, usually yielding excellent yields of amines through a radical chain mechanism entailing H transfer from tin hydride to the derived *N*-(tributylstannyl)aminyl radical (Scheme 7).^{23–27} Until very recently, the AIBN-initiated reaction with Bu₃SnH, first documented by Samano and Robins in 1991,²³ provided the only radical method for the reduction of azides to primary amines among a plethora of the reported nonradical ones.²⁸

Stannylaminyl radicals produced from α -aryl/heteroaryl-substituted aliphatic azides cleanly form rearranged imines through 1,2-migration (see **Radical Rearrangements: Ester-Substituted Radicals and Hydrogen Atom Migrations**) of the aryl/heteroaryl group from the α -carbon to the

Scheme 7 Radical reductions of aromatic and aliphatic azides via stannylaminyl radicals.

Scheme 8 Radical rearrangements with stannylaminyl radicals derived from aliphatic azides.

aminyl nitrogen (Scheme 8a).²⁹ Analogous radical migrations are quite unusual with other aminyl radicals. Such stannylaminyl radical rearrangement has been usefully applied to a radical synthesis of phenanthridine compounds from readily available 6-fluorenyl azides.²⁹

Moreover, under standard conditions, stannylaminyl radicals arising from certain 2-azido-substituted 7-azabicyclo[2.2.1]heptanes strikingly rearrange to the corresponding ring-expanded diazabicyclooctenes, which are valuable synthetic precursors of some α -mannosidase inhibitors (Scheme 8b).³⁰ Such a radical rearrangement was originally claimed to occur via 1,2-migration of a bridgehead alkyl carbon atom. However, since radical 1,2-shifts of alkyl carbons are virtually unknown, a ring-opening/ring-closure sequence should be more likely involved.

Cyclic ketones and ketoesters bearing 2-azidoethyl or 3-azidopropyl α -substituents form ring-expanded lactams by very efficient 5- or 6-exo-cyclizations of nucleophilic stannylaminyl radicals onto the ketone carbonyl groups (Scheme 9a,b).^{31,32}

Scheme 9 Cyclizations of stannylaminyl radicals onto carbonyl groups.

These peculiar stannylaminyl cyclizations enable facile access to otherwise poorly accessible medium-sized lactams. Similarly efficient 3-exo cyclizations of stannylaminyl radicals onto adjacent ketone groups offer a valuable entry to *N*-acyl-protected α -amino esters from easily available cyclic (and also acyclic) α -azido- β -keto esters (Scheme 9c).^{33,34}

It has been established that stannylaminyl radicals derived from aliphatic azides can also perform easy intramolecular addition to electrophilic cyano group in both 5-exo and 6-exo fashion.³⁵ Upon usual treatment with Bu_3SnH /AIBN, α -(2-azidoethyl) and α -(3-azidopropyl)-substituted malononitriles bearing an additional α -allylic substituent furnish good to very good yields of bicyclic hexahydropyrrolopyrroles and hexahydropyrrolopyridines. These bicyclic products are the result of fast 5- and 6-exo cyclization of stannylaminyl radicals onto either malononitrile cyano group, followed by 5-exo cyclization of the cyclized aminoiminyl radicals onto the alkene moiety (Scheme 10).³⁵

Furthermore, in 2009 Sammis *et al.* reported some unprecedented instances of intramolecular addition of stannylaminyl radical to alkenes.³⁶ Despite enhanced nucleophilic character, stannylaminyl radicals produced under typical conditions from 1-silyloxy-substituted 5-azido-1-penten-1-ones and

Bu_3SnH /AIBN were nevertheless fairly able to perform 5-exo cyclization onto the electron-rich silyl enol ether moiety yielding good yields of isolated 2-silyloxymethylpyrrolidines. Two representative examples are shown in Scheme 11.³⁶

These rather surprising stannylaminyl radical cyclizations opened the way to an easy access to 2-hydroxymethylpyrrolidine compounds, which are

Scheme 10 Cyclizations of stannylaminyl radicals onto cyano groups.

Scheme 11 Cyclizations of stannylaminyl radicals onto silyl enol ethers.

of significant interest in the synthesis of polyhydroxylated alkaloids and also of D-ribitol sugars. The authors next reported a useful stereochemical study of their new cyclization reactions. Trans diastereoselectivities of substrates with alkyl or aryl substitution at C₃ have been found to be high to very high regardless of olefin geometry or substitution pattern (Scheme 12). With electronegative substituents adjacent to the silyl enol ether, only *Z*-silyl enol ethers provide high trans diastereoselectivities. Furthermore, temperature, steric size of the silyl group,

Scheme 12 Stannylaminyl radical cyclizations onto methyl- and phenyl-substituted silyl enol ethers.

and sterics and electronics of the tin hydride reagent affect the selectivity only to a modest extent.³⁷

The latest discovery of new effective stannylaminyl radical cyclizations onto electron-rich alkene acceptors provides further very attractive perspectives on the possible application of azides to the radical construction of nitrogen heterocycles.

The chemistry of azides as radical acceptors has long been dominated by the intermolecular reactions with tributyltin radicals; however, the popular adoption of these radicals is discouraged by the known toxicity of organotin compounds and, furthermore, the serious drawbacks connected with full removal of toxic organotin residues from the reaction mixtures. Fortunately, at the turn of the century several original studies of the radical reactivity of azides have disclosed that other benign heteroatom-centered radicals including silyl, germyl, and indyl could be promising substitutes for tributyltin radical. In refluxing toluene, many substituted phenyl azides and additional alkyl azides afford varying yields of reduced amines via isolable *N*-silyl derivatives upon reaction with triethylsilane in the presence of 1,1'-azobis-cyclohexane-1-carbonitrile (ACCN) initiator and additional *tert*-dodecanethiol as a “polarity reversal catalyst.”^{38,39} These reactions most likely occur through a radical chain mechanism entailing key H transfer from the (electrophilic) alkanethiol to a (presumably nucleophilic) *N*-triethylsilylaminyl radical derived from the addition of a primary triethylsilyl radical to the azide (Scheme 13).³⁸

Scheme 13 Radical reductions of aromatic azides with triethylsilane.

Under strictly comparable conditions, analogous aromatic/aliphatic azides are reduced to primary amines by tributylgermanium hydride via a similar radical chain mechanism involving the plausible intervention of *N*-(tributylgermyl)aminyl radicals.⁴⁰ The radical azide reactions with triethylsilane and tributylgermanium hydride usually afford aromatic amines in high to very high yields but give rise to the aliphatic ones only to a limited extent. This fact seems to indicate that aromatic azides might act as notably stronger acceptors of triethylsilyl and tributylgermyl radicals than the aliphatic counterparts. However, a subsequent work of Chatgililoglu *et al.* suggests that alkyl and aryl azides should be comparably able to intercept tris(trimethylsilyl)silyl radical (see **Silanes as Reducing Reagents in Radical Chemistry**). In fact, water-soluble alkyl and aryl/heteroaryl azides **14–17** were always found to furnish excellent yields of primary amines upon reaction with (TMS)₃SiH/ACCN in water at 100 °C in the presence of a catalytic amount of ambiphilic 2-mercaptoethanol (Scheme 14).⁴¹

Aliphatic and aromatic azides seem to have a strong propensity to trap dichloroindyl radicals even under very mild conditions to give the corresponding *N*-indylaminyl radicals after usual loss of dinitrogen. It has been observed that, in acetonitrile solution at 0 °C, a variety of phenyl and alkyl azides undergo fast reaction with only dichloroindium hydride affording good to excellent yields of primary amines after hydrolysis of the resulting reaction mixtures.⁴² These reactions do not

require the presence of any added radical initiator, but in certain cases the reaction rate is clearly enhanced by the presence of a suitable initiator like triethylborane; moreover, with certain azides, the presence of 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO) has been found to cause evident inhibition of the usual reduction. It is therefore plausible that these very mild azide reductions should entail a radical chain mechanism based on fast H transfer from the indium hydride to smoothly formed indium-bound aminyl radicals (Scheme 15).⁴² It is noteworthy that dichloroindium hydride has been found to cleanly convert phenyl azide into aniline even in the presence of a readily reducible substituent such as iodine. This finding would substantiate a special aptitude of the azido group for trapping dichloroindyl radical. Indeed, silyl,^{12,18,38} germyl,⁴⁰ and stannyl^{12,18} radicals are generally found to achieve iodine abstraction from aromatic and aliphatic iodoazides in preference to addition to the azido moiety.

Under identical experimental conditions, dichloroindium hydride transforms a variety of aliphatic and aromatic azidonitriles into cyclized pyrrolidin-2-imines in virtually quantitative yields (Scheme 16).⁴² These amidine products are presumably due to highly efficient 5-exo cyclization of transient indium aminyl radicals onto the internal cyano group. Such data interestingly suggest that (dichloroindyl)aminyl radical should be capable of performing intramolecular addition to the electrophilic cyano group in an even more effective fashion than the tributyltin-substituted congener.

Indium aminyl radicals have also been found to act as distinctive intermediates in unprecedented transformations of aliphatic azides bearing suitable electron-withdrawing substituents in the side chain. In light of our new EPR spectral observation that photolysis at room temperature of accessible

Scheme 14 Radical reductions of aromatic and aliphatic azides in water with tris(trimethylsilyl)silane.

Scheme 16 Radical reactions of dichloroindium hydride with azidonitriles.

allylindium dichloride brings about homolytic fragmentation of the carbon–indium bond yielding allyl and dichloroindyl radicals, we have examined the photochemical reactions of that indium reagent with the azides **18a,b** shown in Scheme 17.⁴³ In benzene solution at room temperature, the reaction with azido ester **18a** gives rise to significant formation of the allylated amine **19a** which spontaneously affords the cyclized piperidinone **20** in good overall yield (Scheme 17a). Chloroazide **18b** is similarly transformed into the corresponding amine **19b**, from which the cyclized pyrrolidine **21** finally arises to a comparable extent (Scheme 17b). The allylated amines **19a,b** are reasonably formed through a tandem radical process involving fast 1,5-H transfer reaction of initial dichloroindium aminyl radical, followed by allylation of the (electrophilic) translocated carbon radical by the (nucleophilic) allylindium reagent (Scheme 17a).⁴³

It is worth noting that allyltributylstannane fails to react with azides **18a,b** under the same photochemical conditions, probably because the ensuing stannylaminyl radical fails to undergo analogous H-transfer reaction. Some comparative theoretical studies actually indicate that the 1,5-migration step should be somewhat more feasible with (dichloroindyl)aminyl radical than with the (trimethyltin)aminyl one (Scheme 18 and Figure 1).⁴³

Scheme 17 Light-induced radical reactions of aliphatic azides with allylindium dichloride.

Scheme 18 Intermediates and transition states (TS) entailed in calculations on 1,5-H transfer reaction of trimethyltin- and dichloroindium-aminy radicals (Metal = Me_3Sn , Cl_2In).

The overall results obtained with aliphatic and aromatic azides and “green” silyl, germyl, and, particularly, indyl radicals lead us to believe that the long domination of undesirable tributylstannyl radicals could be soon overcome.

2.2.3 Sulfonyl Azides as Acceptors of Carbon- and Heteroatom-Centered Radicals

Sulfonyl azides as possible radical acceptors remained virtually obscured up to 1996, when

Figure 1 Reaction profiles for 1,5-H shift of trimethyltin- and dichloroindium-aminy radicals (UB3LYP, LanL2DZ ECP). [Ref. 43—Reproduced by permission of The Royal Society of Chemistry. <http://dx.doi.org/10.1039/C001848A>.]

Scheme 19 Radical allylation of sulfonyl/sulfonamidyl radical.

Scheme 20 Radical azido-transfer reaction.

Roberts *et al.* published a study of their radical reactions with allylstannanes as a potential synthetic entry to *N*-allylsulfonamides.¹⁰ In refluxing benzene in the presence of azo-bis-*iso*-butyronitrile (AIBN), arene- as well as alkane-sulfonyl azides generally furnished satisfactory yields of allylsulfonamides, which were the desired allylation products of derived *N*-stannylsulfonamidyl radicals. However, the resultant allylsulfonamides were always accompanied to a notable extent by the corresponding allylsulfones and additional stannyl azides (Scheme 19). These latter unexpected products were believed to arise from tin radical addition to the terminal azide nitrogen, followed by peculiar elimination of an arene or alkane sulfonyl radical from the ensuing 1,3-triazenyl radical (Scheme 20).¹⁰

The peculiar behavior displayed by sulfonyl azides with tin radicals was strictly substantiated by later reactions with carbon radicals. A few years later, in fact, Renaud *et al.* happened to discover that fairly nucleophilic alkyl radicals reacted with both ethanesulfonyl and benzenesulfonyl azide leading to invariable formation of the corresponding alkyl azides.⁴⁴ The outcoming azides were basically ascribed to fragmentation of 1,3-triazenyl radicals analogous to those originally invoked for azidation of tin radicals (Scheme 20), but it was felt that alternate 3,3-triazenyl radicals, due to alkyl radical attack at the internal azide nitrogen, could possibly play some additional role. Conclusive chemical evidence for azido transfer reaction entailing exclusive radical attack at the terminal azide nitrogen came only in 2007 from a study of alkyl radical azidations with benzenesulfonyl azide bearing terminal nitrogen labeled with ¹⁵N.⁴⁵ The distinctive radical

Scheme 21 Radical azidation with ethanesulfonyl azide.

chemistry of the electron-poor sulfonyl azides has been exploited by Renaud *et al.* in highly useful radical azidations of alkyl radical precursors, which are complementary to the well-established nucleophilic and electrophilic azidation methods. An initial protocol for the radical azidation of alkyl iodides and dithiocarbonates was based on reaction with a suitable excess of ethanesulfonyl azide in boiling chlorobenzene in the presence of dilauroyl peroxide initiator. The proposed radical chain mechanism involving key fragmentation of a released ethanesulfonyl radical is described in Scheme 21.⁴⁴

That protocol often provided good yields of the desired aliphatic azides but, owing to long reaction times and problematic purifications of the final azides, it was soon replaced by a faster and milder one using a threefold excess of benzenesulfonyl azide in boiling benzene, in conjunction with hexabutylditin chain transfer and di-*tert*-butyl hyponitrite (DTBHN) initiator (see **Overview of Radical Initiation**).⁴⁴ The protocol with benzenesulfonyl azide was suggested by the known reactions of alkoxyl and benzenesulfonyl radicals with distannanes affording tin radicals as well as by the disclosed preference of tin radicals for reaction with iodide and dithiocarbonate rather than with the azide reagent. The proposed chain reaction is described in Scheme 22.

Such a radical protocol affords aliphatic azides in a range of yields that become very good with secondary and tertiary alkyl iodides/

Scheme 22 Radical azidation with benzenesulfonyl azide.

dithiocarbonates: that is, the precursors of more nucleophilic alkyl radicals (Scheme 23a).⁴⁴ The protocol has been interestingly applied to tandem cyclization/azidation reactions of alkyl iodides⁴⁴ (Scheme 23b) as well as to intermolecular carboazidations of alkenes where the radical azidation process is coupled with the formation of a carbon–carbon bond (Scheme 23c).^{46,47} In these latter tandem reactions, an electrophilic alkyl radical—often derived from α -iodo and α -xanthate ester—adds to an electron-rich terminal alkene giving rise to a secondary/tertiary alkyl radical which then reacts with benzenesulfonyl azide to deliver the final azide. Simple azidations of alkyl iodides as well as carboazidations of alkenes have been interestingly achieved also under tin-free conditions using a comparable excess of benzenesulfonyl azide and triethylborane initiator in aqueous medium at ambient temperature (Scheme 23d).^{48,49}

The synthetic value of these radical azidation processes has been further improved by the replacement of benzenesulfonyl with 3-pyridinesulfonyl azide (PySO_2N_3), a reagent that enables notably easier chromatographic separations of the azide products.⁵⁰ Radical carboazidations with PySO_2N_3 have been usefully applied to the total synthesis of certain alkaloids.^{51–53} For instance, a stereocontrolled carboazidation of a chiral allylsilane with PySO_2N_3 was adopted as a key step in the total synthesis of hyacinthacine A₁⁵² (Scheme 24).

Since methylenecyclohexanes are particularly appealing substrates for the application of the radical carboazidation to natural-product synthesis, a systematic study of the diastereoselectivity of the carboazidation of those unsaturated compounds bearing substituents at positions 2, 3, and 4 has

Scheme 23 Synthesis of various azido compounds via radical azido-transfer reactions.

Scheme 24 Carboazidation of a chiral allylsilane with PySO_2N_3 : application to the total synthesis of hyacinthacine A_1 .

been also performed.⁵⁴ Under the standard conditions of the tin-mediated carboazidation, using PySO_2N_3 as the azidating agent and ethyl iodoacetate as the radical precursor, every investigated methylenecyclohexane afforded the corresponding carboazidated compound **22** in good yield (Scheme 25). 4-Substituted methylenecyclohexanes give *cis*-azides **22a–c** with fairly high stereoselectivity, whereas the 3-substituted ones give preferentially *trans*-azides **22d,e** with similar levels of stereocontrol. Methylenecyclohexane bearing only a primary cyanoethyl substituent at position 2 afforded azide **22f** with no significant stereochemical control, whereas very highly stereoselective production of azide **22g** occurred with methylenecyclohexane bearing an additional *tert*-butyl substituent at position 4. The observed stereochemical trends are explained in terms of preferential axial attack of PySO_2N_3 at the cyclohexyl radical arising from the addition of (ethoxycarbonyl)methyl radical

to the terminal alkene carbon of the original substrate.⁵⁴

Renaud *et al.* subsequently utilized benzenesulfonyl azide together with various 1,6-dienes and 1-en-6-yne in new radical chain reactions initiated by sunlamp irradiation of di-*tert*-butyldiazene (DTBDA).⁵⁵ Under these circumstances, addition of an initial benzenesulfonyl radical to the terminal alkene or alkyne moiety of the appropriate diene/enyne substrate affords a corresponding alkyl/vinyl radical which undergoes 5-exo cyclization onto the additional ethylene moiety. The ensuing alkyl radical undergoes final azidation by the sulfonyl azide leading to usual liberation of a benzenesulfonyl radical for the chain propagation. These azidosulfonylation processes allow the preparation of novel interesting secondary and tertiary azides in moderate to very good yields (Scheme 26a–c).⁵⁵

At the end of this section, it is useful to mention that some chemical information concerning the radical reactivity of sulfonyl azides with dichloroindyl radicals has become available by means of our radical reactions of benzenesulfonyl azide with dichloroindium hydride in acetonitrile at 0 °C (Scheme 15) and with allylindium dichloride in benzene under photochemical conditions (Scheme 17). With dichloroindium hydride, benzenesulfonyl azide only gave reduced benzenesulfonamide in high yield (80%), thus suggesting the exclusive occurrence of *N*-indylsulfonamidyl radical under the adopted very mild conditions.⁴² With allylindium dichloride, the sulfonyl azide afforded a mixture of benzenesulfonamide and *N*-allylbenzenesulfonamide along with comparable

Scheme 25 Carboazidation of 2-, 3-, and 4-substituted methylenecyclohexanes.

Scheme 26 Azidosulfonylations of 1,6-dienes and 1-en-6-yne.

amounts of allylsulfonylbenzene.⁴³ Under more forcing conditions, dichloroindyl radical seemed to display a similar propensity to tin radicals to attack the terminal azide nitrogen, leading to expected release of benzenesulfonyl radical (Scheme 27).

Scheme 27 Light-induced radical reaction of benzenesulfonyl azide with allylindium dichloride.

2.2.4 Miscellaneous Radical Reactions of Aromatic and Aliphatic Azides

Until the end of the last century, the radical chemistry of organic azides has been invariably based on the peculiar propensity of the azido function to behave as a radical acceptor, but latest studies have disclosed that, under radical conditions, both aliphatic and aromatic azides can exhibit further

Scheme 28 Generation of iminyl radicals via α -azidoalkyl radicals.

very interesting options which deserve adequate discussion for a more detailed comprehension of the impressive radical reactivity and connected utility of the whole azide family. In 1997, a paper dealing with new radical chain reactions of benzenethiol with α -azidostyrenes suggested that aliphatic azides might behave as progenitors of iminyl radicals, provided that transient radicals could be generated on the carbon atom attached to the azido function. At room temperature, those thiol reactions furnished virtually quantitative yields of sulfanylated imines and tautomeric enamines, reasonably ascribable to iminyl radicals derived from primary α -azidobenzyl radical adducts by elimination of molecular nitrogen (Scheme 28).⁵⁶

Following this long-neglected information, we have been led to prove that aliphatic azides could actually act as excellent sources of iminyl radicals through a study of the radical reaction of α -azido *o*-iodoanilides **23** with Bu_3SnH (Scheme 29a).⁵⁷ This study was based on earlier observations that aryl radicals derived from analogous iodoanilides rearrange to more stable alkyl radicals via internal 1,5-H transfer reaction. In refluxing benzene in the presence of Bu_3SnH and the usual AIBN initiator, the azido anilides **23** were found to generate in a virtually quantitative fashion α -(aminocarbonyl)iminyl radicals **26**. These intermediates were evidently formed by prompt elimination of dinitrogen from the corresponding α -azidoalkyl radicals **25**, in turn arising from fast 1,5-H transfer reaction of initial aryl radicals **24** (Scheme 29a). Under the reaction conditions, the resulting α -alkyl-substituted iminyls **26** gave high yields of alkanenitriles **28** by selective β -elimination of a carbamoyl radical **27**, along with limited amounts of oxoquinolines **29** due to parallel cyclization onto the internal aromatic ring (Scheme 29b).⁵⁷

Scheme 29 Generation and fate of iminyl radicals from aliphatic azides by 1,5-H radical shifts.

This work has clearly established that aliphatic azides can be regarded as highly efficient sources not only of aminyl radicals but also of the iminyl congeners, which are valuable intermediates in the radical synthesis of a broad variety of nitrogen compounds.^{21,58,59} Aliphatic azides could then lead to valuable applications to iminyl radical chemistry through the possible discovery of adequate synthetic entries to α -azidoalkyl radicals and thence the corresponding iminyls. In a following work, we demonstrated that also aromatic azides are possible precursors of iminyl radicals whenever homolytic ipso attack can occur at the para position of the azido-substituted benzene ring.⁶⁰ The radical reactions of the accessible *N*-methyl-substituted 2-iodo-*p*-azidobenzanilides **30** as well as the corresponding 2-(*p*-azidophenyl)acetanilides **31** with $(\text{TMS})_3\text{SiH}/\text{Et}_3\text{B}/\text{air}$ at room temperature afforded good yields of indolone/quinolinone imine

Scheme 30 Spirocyclic cyclohexadienimines and derived dienones obtained through iminyl radicals generated by ipso-cyclizations of aryl radicals onto aromatic azides.

hydroiodides **32/33**, isolable by direct filtration of the reaction mixtures (Scheme 30). Under these circumstances, the derived aryl radicals underwent smooth five- or six-membered ipso cyclization onto the internal aromatic azide, yielding spirocyclic azidocyclohexadienyl radicals, which in turn exhibited easy extrusion of molecular nitrogen to give cyclohexadienyliminyl radicals and then reduced imines. These last compounds eventually furnished their hydroiodides by further reaction with hydrogen iodide, probably formed by *in situ* hydrolysis of produced tris(trimethylsilyl)iodosilane. Upon conventional acid hydrolysis in methanol/water, all isolated imine hydroiodides **32/33** gave the respective spirocyclohexadienones **34/35** in satisfactory yields based on the original azides (Scheme 30).⁶⁰

Using the corresponding *N*-methoxymethyl (MOM) protected azidoacetanilides, an improved

synthesis of the *N*-unsubstituted quinolinone analogs has been next attained.^{61,62} Moreover, adoption of the MOM-protected azidobenzanilide **36** has enabled an advantageous preparation of the oxindole spirocyclohexanone **37**, an intermediate involved in the synthesis of the potent, selective vasopressin inhibitor **SR121463A** (Scheme 31).^{61,63}

A new intriguing propensity of aromatic azides to form cyclohexadieniminyl radicals has then allowed a straightforward access to both indolones and dihydro-2-quinolones bearing spirocyclohexadienone/-cyclohexanone rings, which are pivotal intermediates in the synthesis of biologically important indole compounds.^{62–64} It is therefore conceivable that aromatic azides could gain future interest in the radical production of a variety of other appealing spirocyclic compounds. The latest studies discussed in this section point out even

Scheme 31 Improved synthesis of *N*-unsubstituted spiroindolone **37** through key spirocyclization of *N*-MOM-protected azidobenzamide **36**.

more thoroughly the unique ability of the organic azides to form an extensive assortment of cyclic and acyclic nitrogen compounds under radical conditions.

2.3 Inorganic Azides

2.3.1 Iodine Azide in the Radical Azidation of Carbon Compounds

Iodine azide (IN_3), while being well known for its ability of ionic addition to olefins, is also known to undergo easy bond homolysis, providing azide and iodine radicals. In light of such promising

Scheme 32 Radical azidation of benzyl ethers with iodine azide.

information, Bols *et al.* have devised a useful protocol for the radical azidation of benzyl ethers using a twofold excess of iodine azide in refluxing acetonitrile. This protocol usually affords good to very good yields of the corresponding α -azidobenzyl ethers (Scheme 32).⁶⁵

Under these circumstances, homolysis of IN_3 results in an azide radical that abstracts a hydrogen atom from the substrate to form a benzylic radical. This radical is oxidized by IN_3 or I_2 to a benzylic cation that combines with the azide ion to give the final azide. Using an analogous radical protocol, various cyclic benzal acetals have been similarly converted by IN_3 to ring-opened 2-azidoethyl- or 3-azidopropyl benzoates via the final reaction of oxidized dioxolanium/dioxanum ion with the azide ion (Scheme 33).⁶⁶

In a subsequent work, Bols *et al.* demonstrated that IN_3 can also bring about highly efficient radical azidation of aldehyde compounds by acting as a powerful radical acceptor of acyl radicals.⁶⁷ Both aliphatic and aromatic aldehydes can be transformed into the respective acyl azides in good yields by simple treatment with 2 equiv of iodine azide in acetonitrile at 0 – 25°C . With certain aldehydes, the presence of a typical radical trap such as *N*-*tert*-butyl- α -phenylnitrone can prevent the usual production of acyl azide, which strictly supports the involvement of a radical reaction mechanism. Moreover, no production of any carboxylic acid ethyl ester can be observed when the usual IN_3

Scheme 33 Radical azidation of cyclic acetals with iodine azide.

reaction is carried out in ethanol solvent, which clearly suggests that the acyl iodide or oxidized acylium ion cannot occur as possible intermediates. Accordingly, the radical chain mechanism shown in Scheme 34 has been proposed for the mild aldehyde azidation. An initially formed iodine (or azide) radical abstracts the aldehyde hydrogen atom, giving rise to an acyl radical. The resulting acyl radical is smoothly trapped by iodine azide, presumably yielding a 1,3-triazenyl radical whose prompt fragmentation would eventually afford an acyl azide as well as an iodine radical for the chain propagation.⁶⁷ Interestingly, if an aromatic or aliphatic aldehyde is allowed to react with IN_3 in refluxing acetonitrile in the presence of sodium azide, the ensuing acyl azide can afford a good yield of the corresponding carbamoyl azide through spontaneous Curtius rearrangement, followed by addition of azide to the isocyanate.⁶⁷ The radical azidation of an aldehyde with IN_3 has been adopted as a key step in a short synthesis of Cherylline dimethyl ether.⁶⁸ However, it is worth mentioning that another study has established that the notoriously hazardous iodine azide can be usefully substituted with $\text{PhI}(\text{OAc})_2/\text{Me}_3\text{SiN}_3$ in the above radical azidation reactions.⁶⁹

2.3.2 Azidoiodinanes in the Radical Azidation of Hydrocarbons

Azidoiodinanes, $\text{PhI}(\text{N}_3)\text{X}$ ($\text{X} = \text{OAc}$, Cl , OTMS , etc.) or $\text{PhI}(\text{N}_3)_2$, are proposed as reactive

Scheme 34 Mechanism of radical azidation of aldehydes with iodine azide.

Scheme 35 Radical azidation of hydrocarbons with 1-azido-1,2-benziodoxole-3-(1H)-one.

intermediates in the widely used azidation reactions involving the combination of PhIO or $\text{PhI}(\text{OAc})_2$ with trimethylsilyl azide or NaN_3 .^{69,70} Attempts to isolate these intermediates usually result in

fast decomposition at -25°C to 0°C with the formation of iodobenzene and dinitrogen. Importantly, in an excellent work that appeared in 1996, Zhdankin *et al.* reported the preparation of some thermally highly stable azidoiodinanes derived from 1,2-benziodoxole by reaction of the corresponding hydroxy compounds with trimethylsilyl azide.⁷⁰ The prepared azidoiodinanes proved to be good azidating agents toward various organic substrates and they could find especial use for direct radical azidation of hydrocarbons at high temperature and in the presence of suitable radical initiators. For example, 2,2,4-trimethylpentane reacted with 1-azido-1,2-benziodoxole-3-(1*H*)-one in refluxing 1,2-dichlorobenzene in the presence of dibenzoyl peroxide to give the corresponding aliphatic azide in 76% yield (Scheme 35a). The proposed radical chain mechanism involves hydrogen atom abstraction by the released 2-iodobenzoyl radical followed by key azidation of the resultant alkyl radical by the azidoiodinane. This chain process affords moderate to good yields of secondary and tertiary azides from several different alkanes (Scheme 35b).⁷⁰ However, in spite of the fact that Zhdankin's azidoiodinanes actually provided the first authenticated examples of reactions of azidating agents toward alkyl radicals, it appears that these azides have since found no practical application to other radical azidation processes.

3 ISONITRILES

3.1 Introduction

Isonitriles are a very unique class of organic compounds, as they are stable derivatives containing formally a divalent carbon, a property they share with very few molecules, such as carbon monoxide and *N*-heterocyclic carbenes (NHCs).⁷¹ They were discovered by Lieke, Gautier, and Hofmann as early as about a century and a half ago, but up to the 1960s only a relatively small number of studies concerning their chemistry were reported.^{72–77} This was probably due to the virtual absence of convenient, generally applicable synthetic methods, as well as to their very penetrating, unpleasant smell. The two classical isonitrile synthesis that had remained for long time the only access to this category of compounds, that is, the “carballyamine

Scheme 36 Resonance in isonitrile structure.

reaction”⁷² and the “alkylation method,”^{72,74} were indeed definitely not suitable for the preparation of appreciable quantities of pure isonitriles. They have been largely replaced now with the more widely applicable “dehydration method,”^{74,75,77} entailing transformation of primary amines into formamides, followed by dehydration either with phosgene (or its precursors) and triethylamine, or phosphorus oxychloride and di-*iso*-propylamine. The ready accessibility of isonitriles by this very general method has caused their chemistry to flourish, not only proving that these compounds are not merely a curiosity in the field of organic chemistry but also indicating that they possess outstanding versatility. Among the most renowned synthetic procedures, the Ritter-type processes⁷⁶ and the Passerini and Ugi reactions are worth mentioning.⁷⁷ The latter are remarkable multicomponent reactions that can easily afford a wide series of functionalized carboxamides, lactams, amino acids, and peptides, usually in high yields and often in a stereoselective way.

As anticipated, the structure of isonitriles can be described in terms of a divalent carbon atom, but in valence bond terms a full description of the isonitrile moiety requires the two resonance structures **38** and **39** (Scheme 36).

Although physical properties indicate that the dipolar contribution (**38**) is the major one, hence accounting for the nucleophilic behavior of the terminal carbon, in terms of radical chemistry the more interesting form is the divalent one (**39**). Indeed, this clearly shows that the isonitrile moiety does not behave, toward radical species, like a *vicinal* radical acceptor/radical donor synthon—that is like a usual unsaturated bond—but instead like a *geminal* acceptor/donor synthon,⁷⁸ where an incoming radical attacks the same carbon atom that will be the new radical center in the resulting imidoyl intermediate **40**. This terminology was first introduced by Curran *et al.* in 1991.⁷⁸ Actually, isonitriles can serve as very efficient radical traps and this section will review the mechanistic and synthetic studies carried out in this field, with outstanding results, in the last decades.

3.2 Radical Addition to Isonitriles and Fate of the Resulting Imidoyl Radicals

Imidoyl radicals are carbon-centered radical intermediates whose spin-bearing carbon atom belongs to a carbon-nitrogen double bond; the R^1 and R^2 groups (Scheme 36) can be alkyls, aryls, or, mainly in the case of R^2 , even heteroatom-containing moieties (e.g., alkoxy, sulfanyl, stannyl, silyl). To our knowledge, the existence of imidoyl radicals was first claimed in 1964 by Shono *et al.*⁷⁹ who proposed their intermediacy in the reactions of cyclohexyl isonitrile with radical sources such as dibenzoyl peroxide, *tert*-butyl perbenzoate, *N*-nitrosoacetanilide, and potassium phenylazoformate. However, apart from coupling or hydrogen transfer, none of the peculiar reactivities of imidoyl radicals was evidenced in that paper, probably as the result of very complicated reaction mixtures and approximate analysis methods. However, it is worth pointing out that this paper provided the first example of radical addition to isonitriles, a method that will be meant to be the main generation source of imidoyl radicals and by all means the most important resource for synthetic applications.^{80,81}

More interestingly, in 1967, Shaw and Pritchard⁸² studied the isonitrile–nitrile isomerization of methyl and ethyl isonitrile catalyzed by di-*tert*-butyl peroxide (DTBP). Although the concerted isonitrile–nitrile thermal (or photochemical) isomerization had been well known for many years,⁸³ they explained the process in terms of a radical chain mechanism involving the addition of (catalytic) methyl radicals to the isonitrile followed by β -scission of the resulting imidoyl radical adduct: the ensuing alkyl radical propagates the radical chain leading to the complete conversion of the starting isonitrile into its cyanoisomer (Scheme 37).^{84,a} A free-radical chain mechanism for the isonitrile–nitrile rearrangement in solution was definitely established by Rüchardt *et al.* in 1983.⁸⁵

As early as in 1968, Saegusa *et al.* reported the first example of addition to isonitriles of a kind of intermediate that had to become very popular in the field of radical chemistry: that is, tributyltin radical (see **Tin Hydrides and Functional Group Transformations**). The reaction of tributyltin hydride with some alkyl isonitriles in the presence of a radical initiator (AIBN) was found to afford the corresponding alkanes and tributyltin cyanide through an addition/fragmentation sequence

Scheme 37 Radical chain for conversion of isonitriles into the corresponding nitriles.

Scheme 38 Radical chain for addition of tin-centered radicals to isonitriles.

analogous to that reported in Scheme 37, in which tin radicals behave like additional chain-propagating species (Scheme 38).⁸⁶

A similar behavior was observed by the same author for phosphorus-centered radicals generated by hydrogen abstraction from diethyl or diphenylphosphine.⁸⁷ However, in this case, the reaction outcome was found to depend on the nature of the isonitrile: *tert*-butyl and benzyl isonitrile gave diethylcyanophosphine together with isobutane and toluene, respectively, whereas cyclohexyl and *n*-hexyl isonitrile yielded the corresponding diethylformimidoyl phosphines, arising from hydrogen transfer from the phosphine to the intermediate imidoyl radical. This result showed that hydrogen atom transfer to the intermediate imidoyl radical may well compete with β -fragmentation both/either in the absence of groups that can be released as

stable radicals and/or in the presence of very good H donors. Indeed, the reaction of tributyltin hydride with cyclohexyl isonitrile gave cyclohexane and tributyltin cyanide,⁸⁶ thus revealing that phosphines are better hydrogen donors than stannanes for imidoyl radicals.

During the 1970s, several papers have appeared^{88–92} dealing with addition of carbon-,^{90–92} oxygen-,^{89,90,92} and sulfur-centered⁸⁸ radicals to isonitriles. Interestingly, in the case of those heteroatom-centered radicals, the fate of the intermediate imidoyls depends upon the nature of both the attacking radical and the alkyl group of the isonitrile. Normally—even in the case of *tert*-butyl isonitrile—with oxygen- or sulfur-centered radicals, β -fragmentation on the O or S side prevails, resulting in scission of the O–Y or S–Y bond of the attacking radicals to give isocyanates or isothiocyanates, respectively (Scheme 39, path a). The only exception is addition of methylsulfanyl radical to *tert*-butyl isonitrile, which gives methyl thiocyanate and *tert*-butyl radical instead of *tert*-butyl isothiocyanate and methyl radical, due to the very strong S–Me bond of the intermediate imidoyl radical (see Ref. 93). Carbon radicals (as well as tin- and silicon-centered radicals)⁹⁴ produce, instead, nitriles through β -fragmentation of the original N–R bond of the isonitrile (Scheme 39, path b). Such reactions have a noteworthy synthetic potential and can be used either as an efficient, easy way to introduce a cyano group into a molecule or—by prior conversion of an amino group into the isonitrile moiety—as a useful deamination method (see below).

It should be noted that imidoyl radicals, when generated either from imines⁸¹ or isothiocyanates (see Section 4.2), can undergo an additional fragmentation reaction, that is, an α -scission

Scheme 39 Fragmentation products for addition of heteroatom-centered radicals to isonitriles.

Scheme 40 α -Fragmentation of imidoyl radicals affording isonitriles.

with formation of an isonitrile. This process has been observed with α -(triphenylmethyl)-,^{95,96} α -(tributyltin)thio-, and α -(arylsulfanyl)-^{97–99} imidoyl radicals^{100,b} (Scheme 40). This would entail that the formation of imidoyls by radical addition to isonitriles can be a reversible process: this conjecture has been supported by some evidence in the case of particularly stable radicals.⁹⁵ This could definitely be an important detail that should be taken into account in designing a radical synthetic project involving isonitriles.

3.3 Structure, Spectroscopy, and Kinetics of Radical Adducts of Isonitriles

The first EPR study (see **Analysis of Radicals by EPR**) on the structure of imidoyl radicals dates back to 1973,¹⁰¹ although in that case imidoyls were generated by hydrogen abstraction from some aldimines. The low observed *g*-values (2.0016) and the β -hydrogen hyperfine splittings suggested that imidoyls are σ radicals with a nonlinear arrangement about the N=C–C bond. Their remarkable stabilization was explained in terms of the mesomeric forms shown in Scheme 41, in which the unpaired electron is stabilized by interaction with the lone pair on nitrogen, similar to what was suggested for the isoelectronic acyl radicals.¹⁰² The low *a*(N) values (1.20–1.85 G), which are in conflict with this kind of stabilization, were accounted for through a spin polarization mechanism that can induce a negative spin density at the nitrogen, thereby somewhat balancing the positive density resulting from resonance. The σ -electronic configuration of imidoyl radicals was confirmed some years later by Davies *et al.*,⁹⁴ who

Scheme 41 Resonance stabilization in imidoyl radicals.

related their structure to that of the parent imines through a mathematical relationship between the EPR $a(\text{H}_\beta)$ constants of the former and the NMR 3J coupling constants of the latter.^{103,c}

A comprehensive EPR study on the spectroscopic properties of imidoyl radicals as well as the kinetics of their basic reactions was carried out by Roberts *et al.* in the subsequent two decades.^{93,104–111} In his seminal papers,^{93,104} he used isonitriles as the source of various α -heteroatom-substituted imidoyl radicals (for comparison purpose, Roberts generated some imidoyls also by hydrogen abstraction from imidates or imines by photolysis with bis(trimethylsilyl) or dicumyl peroxide (Refs 93 and 104)) and calculated some rate constants for both the radical addition and the β -fragmentation processes (Scheme 39, paths a and b). Addition of alkoxyls, for example, was found to be faster ($k \cong 6 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ at 253 K) than that of alkyl radicals but slower than addition of phenyl radicals,⁹¹ whereas β -fragmentation of α -alkoxyimidoyls (Scheme 39, path a) was surprisingly slower ($k = 3.6 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ at 243 K) than that of the analogous α -(alkanesulfanyl)imidoyls. Interestingly, the $a(^{13}\text{C}_\alpha)$ and $a(\text{N})$ values were found to depend upon the nature of the α substituent R^2 (Scheme 41): the more electronegative R^2 is, the greater are $a(^{13}\text{C}_\alpha)$ and the $\text{N}=\text{C}^{\bullet}-\text{C}$ angle, as a result of an increase of the s-character of the semioccupied orbital. At the same time, the ability of R^2 to stabilize the negative charge on C_α enhances the positive spin density on nitrogen and hence the magnitude of $a(\text{N})$. These effects can account for the trend of the $a(\text{N})$ values observed with *tert*-butoxy, *tert*-butyl, *tert*-butylsulfanyl, and (trifluoromethyl)sulfanyl α -substituents (<0.3, 1.8, 5.0, and 5.8 G, respectively). When $\text{R}^2 = \text{SiEt}_3$, the electropositive silicon atom leads to quite a low $a(^{13}\text{C}_\alpha)$ value (29.8 G), whereas its ability to stabilize an adjacent negative charge gives rise to a rather large nitrogen hyperfine splitting (8.6 G). Since the pseudo- π overlap is maximum for a linear geometry, this specific imidoyl radical was hence suggested to be close to linear at C_α , similar to what was proposed for the isoelectronic β,β -bis(trimethylsilyl)- α -(trimethylsilyl)vinyl radical, which has a comparable $a(^{13}\text{C}_\alpha)$ value of 28.1 G.¹¹² This conclusion was nevertheless questioned by some theoretical calculations, which suggested that the radical structure is essentially independent of the electronic nature of the α -substituent, the $\text{N}=\text{C}^{\bullet}-\text{C}$ angle being virtually

constant at about 128° .¹¹³ It is worth noting that addition of silyl radicals to isonitriles was also kinetically studied by laser flash photolysis and was found to be a very fast process ($k = 1.6 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ at 300 K).¹¹⁴

α -(Trialkylsilyl)oxy-substituted imidoyls were generated by Roberts *et al.* through addition of silyl radicals to isocyanates (see also Section 4.1).¹⁰⁶ The addition was found to be considerably exothermic and probably involves early transition states with significant charge separation. The resulting imidoyls are strongly bent σ radicals with *E* and *s-trans* configurations about the $\text{N}=\text{C}$ and $\text{C}-\text{O}$ bonds, respectively, and they have the unpaired electron stabilized by both nitrogen and oxygen lone pairs. The rate of addition decreases along the series $\text{R} = \text{Me} > \text{Et} > i\text{-Pr} > \text{tert-Bu}$. The extremely low reaction rate observed with *tert*-butyl isocyanate ($k_{\text{tert-Bu}}/k_{\text{Me}} \leq 0.011!$) has been accounted for through a perturbational molecular orbital approach where the dominant frontier orbital interaction should occur between the SOMO of the nucleophilic trialkylsilyl radical (a hybrid of Si 3s and Si 3p orbitals) and the lowest unoccupied molecular orbital (LUMO) of the electrophilic isocyanate. Calculations predicted that the latter is a σ orbital primarily antibonding between the carbon atom and the two vicinal heteroatoms. The silyl radical should therefore approach the isocyanate in such a direction as to allow maximum overlap between the two orbitals (Scheme 42). The transition state can then evolve to the W-shaped imidoyl by shift of the silyl group onto the oxygen and concomitant localization of the spin onto the carbon atom. The lower reaction rates observed in the presence of bulky R groups are therefore the result of a steric compression between the *N*-alkyl and trimethylsilyl groups in the transition state.

Isonitriles can presumably be attacked by boron-centered radicals as well.^{107,108} Indeed, borane radical anions $\text{H}_3\text{B}^{\bullet-}$ and $\text{H}_2\text{B}^{\bullet}\text{CN}^-$, generated from the corresponding anions H_4B^- and H_3BCN^- by hydrogen abstraction with *tert*-butoxyls, have been found to displace alkyl radicals from alkyl isonitriles. While the expected C-borinated imidoyl radicals were not detected in any case, the reaction presumably entails their intermediacy, although an alternative mechanism involving an electron transfer from the borane radical anion to the isonitrile must not be excluded. Analogous alkyl radical displacements from alkyl

Scheme 42 Transition state for addition of silyl radicals to alkyl isocyanates.

isonitriles were also observed with boryl radicals ($\text{NH}_3 \rightarrow \text{BH}_2^\bullet$), generated by hydrogen abstraction from the ammonia–borane complex, but also in these cases no imidoys were detected.¹¹⁰

Imidoyl radicals were instead clearly observed in the reactions of alkyl isonitriles with phosphorus-centered radicals, obtained by hydrogen abstraction from dimethyl- or diethylphosphine–borane complexes. Some other phosphorus-substituted imidoys were also reported in Ref. 104.¹⁰⁹ Although it is not certain whether the attacking radical is a phosphinyl ($\text{R}_2\text{P}^\bullet \rightarrow \text{BH}_3$) or a phosphoranyl radical [$\text{R}_2\text{P}^\bullet(\text{BH}_2)\text{H}$] (with the former probably preferred), these imidoys, contrary to most congeners, are particularly stable toward β -fragmentation (see also Ref. 93), with the *N*-*tert*-Bu derivative still observable even at 293 K.

Other imidoyl radicals were later obtained by the addition of 1,1-bis(alkoxycarbonyl)alkyl- and tris(ethoxycarbonyl)methyl radicals to methyl and *tert*-butyl isonitrile.¹¹¹ These imidoys are strongly bent at C_α and the extent of bending increases with the number of electron-withdrawing groups attached to C_β , as expected from the previous studies.⁹³ More interestingly, addition of those electrophilic alkyl radicals to the nucleophilic carbon atom of isonitriles were found to be faster than that of unsubstituted (and hence nucleophilic as well) alkyl radicals, as a result of charge-transfer interactions in the transition state (Scheme 43). Therefore, as has been already emphasized for many radical processes, polar effects should be definitely taken into account in planning profitable synthetic procedures involving radical addition to isonitriles: substituents that increase both the nucleophilicity of the isonitrile and the electrophilicity of the attacking radical might provide a proper basis for a more likely success.

Scheme 43 Polar effects in addition of electrophilic radicals to isonitriles.

Analogous effects were suggested to explain the substituent effects observed by Kenttämäa *et al.* in the gas phase in the reaction of *tert*-butyl isonitrile with aryl radicals generated in a Fourier transform ion cyclotron resonance mass spectrometer.¹¹⁵ The efficiency of that reaction strictly follows the calculated electron affinity ordering of the aryl radicals and hence the authors concluded that the rate-determining step in the cyano-group abstraction from *tert*-butyl isonitrile by aryl radicals is the addition of the aryl radical to the isonitrile, with polar effects playing a crucial role in lowering the energies of the corresponding transition states. Addition of protonated 2-, 3-, and 4-dehydropyridine radicals to *tert*-butyl isonitrile in the gas phase was also studied¹¹⁶ and the different behavior of the 4-isomer, which gave predominantly HCN abstraction instead of the usual cyano-group transfer, was explained in terms of different charge and spin delocalization in the intermediate imidoyl radicals.^{117,d}

A thorough investigation on sulfanyl radical addition to isonitriles was carried out by us and Walton,^{118,119} who characterized the resulting thioimidoyl radicals by EPR spectroscopy and studied the β -scissions of their NC'S-C bonds by variable-temperature experiments. The obtained fragmentation rate constants and activation energies show that, at room temperature, the scission rates, although depend on the stability of the released alkyl radicals, are in any case very fast. Experiments carried out on unsymmetrical thioimidoys showed that competitive β -scission of the alkyl–N bond did not occur in any case, even in the simultaneous presence of a primary alkyl on the sulfur and a tertiary alkyl on the nitrogen. So fast is the fragmentation that practically every kind of C-centered alkyl (but, unfortunately, neither aryl nor vinyl) radical can be efficiently produced by this route at $T \geq 20^\circ\text{C}$.

($10^5 < k_f < 10^6 \text{ s}^{-1}$ at 298 K). Thermodynamic stabilization of the released radical plays, however, an important role: going, for example, from *S*-*n*-alkyl to *S*-*tert*-butyl causes an increase of the fragmentation rate of nearly two orders of magnitude at 200 K, and so fast is the release of resonance-stabilized radicals (e.g., benzyl) that the corresponding thioimidoyls could not be detected by EPR even at the lowest accessible temperatures.

Data collected on other heteroimidoyls revealed that oxyimidoyls, as expected,⁹³ exhibited slightly slower (≥ 16 times) fragmentations compared to those of analogous thioimidoyls, whereas theoretical calculations put forward for selenoimidoyls showed the lowest fragmentation rates. The competition between β -scission and 5-exo ring closure of *S*-but-3-enyl-substituted imidoyl radicals was also kinetically studied, showing that cyclization can prevail over fragmentation only at low temperatures (e.g., 200 K).

Density functional theory (DFT) computations on oxy-, thio-, and selenoimidoyls ($\text{RNC}^{\bullet}\text{-XR}'$, $\text{X} = \text{O}, \text{S}, \text{Se}$) gave further support to the postulated bent trans (W) σ structure of heteroimidoyl radicals and reproduced well the observed selectivity for *S*-alkyl with respect to *N*-alkyl fragmentation. Calculations also showed that, for all kinds of imidoyls, the scission preferentially occurs from the *s*-cis rotamer ($\text{NC}^{\bullet}\text{-X}$ bond) of the imidoyl radical. Since thio- and selenoimidoyls (but seemingly not oxyimidoyls) adopt a more stable *s*-trans conformation, but the rotation barriers around the $\text{NC}^{\bullet}\text{-X}$ bond ($E_a \cong 5\text{--}6 \text{ kcal mol}^{-1}$) are always lower than those for β -fragmentations ($E_a \cong 10\text{--}11 \text{ kcal mol}^{-1}$), those radicals can only fragment through prior rotation of the $\text{NC}^{\bullet}\text{-X}$ bond. Loss of the alkyl group at the X side seems therefore to resemble the anti-elimination process typical of many ionic reactions.¹²⁰

As far as the structure of imidoyl radicals is concerned, it is also worth noting that some experimental results coupled with theoretical calculations—although performed with semiempirical methods—suggest that the geometry of these intermediates could suitably change in the presence of resonance-stabilizing groups such as the carbon–carbon double bond of a vinyl moiety.¹²¹ Indeed, the geometry of the products obtained by vinyl radical addition to *tert*-butyl isonitrile was accounted for through an isomerization mechanism involving rotation around the vinyl carbon–carbon bond, transformed into a single bond by resonance

Scheme 44 Conjugation effects on the structure of imidoyl radicals.

effects that would convert the α -vinylimidoyl into an α -keteniminyl alkyl radical (see also Section 4.3). Calculations predicted for the imidoyl of Scheme 44 a practically linear assembly of the N-C-C moiety, with most of the spin density localized on the C_γ atom, a structure also suggested for isoelectronic β,γ -unsaturated acyl radicals.^{122,123}

To conclude, it is worth noting that Yamago, Yoshida, *et al.* performed some comparative experimental and theoretical studies on radical additions to isonitriles and their analogous geminal acceptor/donor synthon carbon monoxide.¹²⁴ The results show that isonitriles are much better radical traps than carbon monoxide, specifically when stabilized radicals are involved. This stems from thermodynamic rather than kinetic effects, since activation energies are low for both kinds of reactants, whereas only isonitriles give rise to strongly exothermic additions, affording more stable radical intermediates (imidoyls vs acyls). As a result, not only do isonitriles behave like a valid substitute for CO (to circumvent decarbonylation of the intermediate isoelectronic acyl radicals), but they are also a suitable complement in radical-mediated C1 homologation reactions in the case of stabilized radicals that cannot react efficiently with CO.¹²⁵

3.4 Synthetic Applications

Examples of radical attack to isonitriles are copious, and isonitriles undoubtedly represent the lion's share among the existing methods of generation of imidoyl radicals. For synthetic applications of imidoyl radicals generated from imines or imine derivatives, see Ref. 81. Actually, we have shown that isonitriles have been the first source of imidoyls⁷⁹ and they have been used for all

the seminal studies about their general reactivity. As far as synthetic applications are concerned, the first reported example can be considered the work published in 1980 by Barton,⁹⁷ who was the first to recognize the potential of this reaction in organic synthesis and was therefore a pioneer in this field as well. Actually, he did not do anything else but realize that the already well-known β -fragmentation reaction of *N*-alkylimidoyl radicals could be a breakthrough as a deamination method. Indeed, he applied this idea in the defunctionalization of steroidal amines⁹⁷ and aminoglycosides such as the antibiotic neamine,¹²⁶ by prior conversion of those amines into the corresponding isonitriles, followed by reaction with tin-centered radicals. Some years later, Giese *et al.* showed that, by reacting alkyl isonitriles with tris(trimethylsilyl)silyl radicals, the ensuing alkyl radicals could add to alkenes. Hence, he demonstrated that, besides defunctionalization, that is, replacement of amino groups with hydrogen atoms, the alkyl radicals arising from C–N fragmentation of imidoyls could be exploited for other synthetically convenient reactions such as formation of new C–C bonds (Scheme 45).¹²⁷

If we change the point of view from the isonitrile to the attacking radical, we can exploit the same

Scheme 45 Radical addition to isonitriles as both a deamination and a functionalization method.

Scheme 46 Radical addition to isonitriles as a cyanation method.

β -scission reaction not as a deamination but rather as a radical cyanation method, as Stork *et al.* did in the same decade.¹²⁸ They showed indeed that alkyl and vinyl radicals arising from cyclization of bromoacetals can be efficiently trapped by *tert*-butyl isonitrile to give nitriles in good yields (Scheme 46). Aryl radicals can be used as well in this kind of radical cyanation reaction, as proved by Jones by reacting H-unprotected indol-2-yl radicals with *tert*-butyl isonitrile to obtain 2-cyanoindoles.^{129,130,e}

Later on, Barton again used his renowned method of radical generation from esters of *N*-hydroxypyridine-2-thione to invent a novel procedure for carboxyl group labeling involving isonitriles.¹³¹ His method entails thiohydroxamic ester-mediated generation of an alkyl radical, followed by addition to a suitable isonitrile to give a ¹³C-labeled imidoyl radical. Trapping of the imidoyl by the starting thiohydroxamate affords an adduct that can be easily hydrolyzed to the corresponding carboxylic acid. Since the starting thiohydroxamic ester is smoothly accessible from the same derivative, the overall process can serve as a method to incorporate ¹³C in the carboxylic acid simply by using an isotopically enriched isonitrile. This method can be useful for labeling the carboxyl group of prostaglandins and the side-chain carboxyls of peptides (Scheme 47).

In principle, the presence of the N atom in the structure of radical adducts to isonitriles makes them very attractive intermediates for the synthesis of *N*-heterocycles. Nevertheless, the first examples of this application entailed generation of imidoyl radicals from imines or imidoyl derivatives,⁸¹ and it was not until 1991 that generation of imidoyl radicals from isonitriles was successfully employed in the synthesis of heterocycles thanks to the brilliant and pioneering work by Curran.⁷⁸ He accomplished indeed the first examples of [4 + 1] radical annulation by reacting aryl isonitriles with alkyn-5-yl radicals, in turn generated from

Scheme 47 Radical addition to isonitriles as a ^{13}C -labeling method for carboxylic acids.

the corresponding iodides. The reaction afforded cyclopenta-fused quinolines through a mechanism entailing addition of the alkynyl radical to the isonitrile, followed by 5-*exo*-dig-cyclization of the resulting imidoyl onto the carbon–carbon triple bond of the original alkynyl radical and eventual ring-closure of the produced vinyl radical onto the *N*-aryl ring (Scheme 48). The quinoline products were obtained as mixtures of isomers, as expected on the basis of the previously observed¹³² competitive six- and five-membered cyclizations of the intermediate vinyl radical.

With that result in his hands, the step toward more interesting applications was on his doorstep. The cyclopenta-fused quinoline moiety is in fact one of the main structural features of the camptothecin family, a group of molecules that has moved to the forefront of research in the treatment of solid tumors by chemotherapy and as antiviral drugs. Curran used his [4 + 1] radical annulation strategy as an outstanding breakthrough for the synthesis of (20*S*)-camptothecin and a wide series of approved drugs (mappicine,

topotecan, and irinotecan) and drug candidates (silatecans) (Figure 2), simply starting from suitable alkynyl-substituted radical precursors.^{133–140} The stereochemical requirements of the synthesis were fulfilled using enantiomerically pure alkynes, whereas the regiocontrol was achieved, when necessary, using *ortho*-(trimethylsilyl)-substituted aryl isonitriles. The overall procedure was therefore an asymmetric, regioselective, and widely applicable protocol that made accessible dozens different compounds.

During the 1990s, we carried out analogous reactions leading to heterocyclic compounds^{141–143} by reacting aromatic isonitriles with alkyl and sulfanyl radicals bearing a cyano-substituted side chain, thereby establishing the feasibility of attack of imidoyl radicals to the $\text{C}\equiv\text{N}$ triple bond. A few [4 + 1] annulation strategies involving a cyano group were also used by Curran: see Refs 136 and 139. The

overall reactivity of imidoyl radicals suggests that they are somewhat nucleophilic species, so that there was no surprise they could react well with the carbon atom of nitriles. This is also in agreement with the resonance form shown on the right side of Scheme 41, where the negative charge on the carbon atom plays a role in increasing the energy level of the radical SOMO, hence favoring SOMO–LUMO interactions with electron-deficient acceptors. An unprecedented trimolecular version of the radical addition tandem cyclization strategy was first carried out with a three-component system comprising an aromatic isonitrile, AIBN, and phenylacetylene.¹⁴¹ The 2-cyanoprop-2-yl radical arising from decomposition of AIBN adds to the terminal carbon of the alkyne to give a vinyl radical that attacks the isonitrile; the resulting imidoyl gives a tandem cyclization affording a quinoxaline derivative (Scheme 49). The formation of a unique quinoxaline isomer, rather than due to ring strain, seems a characteristic of the intermediate iminyl radical, since the analogous vinyl radical gives competitive cyclizations onto the aryl ring (Scheme 48).

Similar results were also obtained by more usual two-component reactions carried out with cyano-substituted alkyl and sulfanyl radicals, the former obtained by photolysis of the corresponding iodides and the latter by hydrogen abstraction from thiols or photolysis of disulfides.¹⁴² In the case of *alkanesulfanyl* radicals, a significant competition between cyclization and C–S fragmentation of the imidoyl radicals was observed,⁸⁸ in line with the kinetic results obtained later on (Section 3.3). For

Scheme 49 [4 + 1] Radical annulation with isonitriles involving iminyl radicals.

another example of tandem cyclization triggered by attack of an alkylsulfanyl radical to an isonitrile, see Ref. 144.^{118,119} More profitable results could be obtained with cyano-substituted *arenesulfanyl* radicals, due to the stronger C–S bond. Cyclopenta-, thieno-, and benzothieno-quinoxalines have been synthesized with this methodology.

In those papers,^{141,142} the authors also showed that, in the absence of good oxidizing agents, isonitriles can be involved in the oxidation step of the cyclohexadienyl precursors of the final aromatic compounds: this might answer, at least to some extent, a *vexata quaestio* in the field of homolytic aromatic substitutions (see **Radical Arylations**).⁷⁸ The intermediacy of the C-unsubstituted imidoyl **41**, evidently associated with the intervention of the isonitrile in the aromatization process, was indeed clearly demonstrated by the occurrence, in the presence of phenylacetylene, of competing [4 + 2] and [3 + 2] annulations, affording two isomeric quinoxalines, a behavior that is typical of annulations involving imidoyl radicals (Scheme 50). It is not clear, though, whether isonitriles are implicated through a direct hydrogen abstraction—a mechanism that is the disproportionation analog of a radical–radical reaction—or a two-step reaction entailing a single electron transfer (SET) followed by proton transfer.^{145,f} This behavior was also observed in some cyclizations of biphenyl-2-yl isonitrile, and

Scheme 50 Involvement of isonitriles in aromatization of cyclohexadienyl radicals.

Scheme 51 Synthesis of five-membered heterocycles by sulfanyl radical addition to isonitriles.

its 2',3',4',5',6'-*d*₅-analog, to phenanthridine derivatives under various radical conditions.^{141,146,g}

The application of radical addition to isonitriles as a synthetic route to heterocycles has been further extended by Smith, who carried out [4 + 1] annulations using vinyl rather than aryl isonitriles as radical traps for alkynyl- or cyano-substituted alkyl radicals.¹⁴⁷ That paper also suggested the occurrence of a novel cyclic imidothiocarbonyl radical, generated by intramolecular aryl radical addition to an isonitrile moiety. Some mechanistic aspects of this reaction remain however unclear, since the postulated imidothiocarbonyl could be intermolecularly trapped only by an electron-rich alkene such as *tert*-butyl vinyl ether, in contrast with the general nucleophilic behavior exhibited by imidothiocarbonyl radicals.

A definite pioneer in the use of isonitriles in radical-mediated synthesis of heterocycles has been Bachi, who, during the 1990s, followed the way paved by Saegusa 20 years earlier⁸⁷ by exploiting sulfanyl radical addition to isonitriles for the synthesis of five-membered nitrogen heterocycles.^{148–152} As an example, treatment of the alkenyl-substituted isonitriles **42**, easily accessible from glycine imines, with an arene- or alkanethiol in the presence of AIBN afforded the *cis*- and *trans*-pyrroline derivatives **44** in high yields (Scheme 51). The use of mercaptoethanol gave instead a mixture of *cis*- and *trans*-pyroglutamates **45** probably through hydrolysis of a spirothioxolanepyrrolidine intermediate.¹⁴⁸

Of the two possible fragmentation side reactions that, in principle, imidothiocarbonyl radical **43** could undergo, that is, C–N bond breaking leading to deamination of the starting material, or C–S bond scission leading to an isothiocyanate, only the latter competed to some extent, especially when the scission yielded a fairly stable radical ($\text{R}^5 = \text{CH}_2\text{CO}_2\text{Me}$). However,

in those cases, adequate temperature adjustment allowed control over the two competing reactions.

As far as stereochemistry is concerned, whereas no or low diastereoselectivity was observed in the formation of the above pyrrolines and pyroglutamates (Scheme 51), an efficient stereocontrol was achieved with suitably designed starting materials bearing a bulky TBDMS–O (*tert*-butyldimethylsilyl, TBDMS) group vicinal to the site of radical addition.¹⁴⁹ This methodology was used as the key cyclization step in the stereo- and enantioselective synthesis of (±)- and (–)- α -kainic acid, the prototype of a group of neuroexcitatory amino acids that are important substrates in physiological and pharmacological studies of the central nervous system.^{150–153,h}

Analogous cyclizations of alkenyl- as well as alkynyl- isonitriles to pyrroline and pyroglutamate derivatives have been improved by the use of microwave flash-heating technology, which gave significantly superior results in terms of both reaction times and yields.¹⁵⁴ The same authors also developed an equivalent procedure based on polymer-supported alkenyl isonitriles.¹⁵⁵

Indoles are another important class of heterocycles that are accessible by radical isonitrile chemistry. *ortho*-Alkenyl-substituted aromatic isonitriles have indeed been successfully employed by Fukuyama *et al.* in a tin radical-mediated synthesis of indole derivatives bearing a stannylated moiety that is available for further manipulation through the Stille palladium-mediated coupling with aromatic or unsaturated halides or triflates (Scheme 52).^{156–158} This methodology has been also effectively used in the preparation of key intermediates for the total synthesis of some indole alkaloids.^{157,158} A variant of this procedure was developed by the same author through radical cyclization of *ortho*-alkenyl-substituted thioanilides.¹⁵⁹

Rainier *et al.* demonstrated that a very efficient synthesis of indoles can be carried out also with *ortho*-alkynyl-substituted aryl isonitriles (Scheme 53).¹⁶⁰ Five-membered ring-closure could be conveniently accomplished with either stannyl or sulfanyl radicals, and the presence of a TMS group linked to the alkyne moiety hampered concomitant formation of the six-membered cyclization quinoline product. The intermediate indolenines could be efficiently trapped by both nucleophilic radical precursors, that is, stannane and thiol, to give the final substituted indoles.

Scheme 52 Synthesis of indoles by tin-radical-mediated cyclization of alkenyl isonitriles.

Scheme 53 Synthesis of indoles by tin/sulfanyl-radical-mediated cyclization of alkynyl isonitriles.

Yamago, Tokuyama, *et al.* have shown that indole derivatives can also be obtained by tin radical-mediated reaction of *N*-(2-alkenylphenyl) (phenyltelluro)imidates produced by thermal radical reaction of isonitriles with α -aminomethyltellurides.¹⁶¹ In this case, the intermediate imidoyl radicals cannot cyclize because of the very fast phenyltellanyl group transfer from the α -aminomethyltelluride. However, the same imidoyls can be regenerated by reaction of the resulting telluroimidates with tin radicals, and under these conditions they give ring-closure to indoles in high yields.

Yamago, Yoshida *et al.* have carried out a comprehensive study on the radical reactions involving telluro-derivatives and isonitriles.^{124, 161–166} Although only one example is related to the synthesis of heterocycles,¹⁶¹ the whole analysis is nonetheless of valuable synthetic interest, since it gave access to compounds susceptible to many further transformations. Their procedure involves

thermal or photolytic generation of alkyl or acyl radicals from the corresponding aryltellanides, followed by radical addition to an isonitrile and final aryltellanide group transfer from the starting telluro derivatives to the intermediate imidoyl radicals (Scheme 54).^{124, 162, 163, 166} The produced telluroimidates can be converted into amides or aldehydes and the reaction can be also captivatingly applied to three-component systems including silyltellurides, isonitriles, and either carbonyl compounds¹⁶⁴ or imines.¹⁶⁵ Appealing classes of compounds synthesized by this methodology include acyl glycosides,¹⁶² α -acylamides,¹⁶³ α -hydroxy carbonyl compounds,¹⁶⁴ and α -aminoacid derivatives.¹⁶⁵

We studied another efficient three-component radical cascade reaction with isonitriles, entailing the photolytic reaction between aromatic disulfides, alkynes, and isonitriles, affording β -arylthio-substituted acrylamides or acrylonitriles in fair yields (Scheme 55).¹²¹ The procedure involves the addition of photolytically generated sulfanyl radicals to the alkyne, followed by the attack of the resulting vinyl

Scheme 54 Radical reactions of isonitriles with telluro derivatives.

Scheme 55 Three-component radical reactions with isonitriles.

radicals to the isonitrile. The eventual imidoyl radical is trapped by a nitro-derivative (route a, *m*-DNB = *m*-dinitrobenzene) or undergoes β -fragmentation (route b). In the absence of either process, the imidoyl is unable to sustain the radical chain and only the starting material is recovered, possibly as the result of reversible addition of vinyl radicals to the isonitrile. The reaction provides very easy access to potentially useful polyfunctionalized alkenes through a very selective tandem addition sequence.

In those reactions, a lower or even inverted preference for either geometrical isomer was observed with respect to related hydrogen abstraction reactions by the same vinyl radicals. This was explained in terms of both/either transition-state interactions in the addition step to the isonitrile and/or isomerization of the final quasilinear imidoyl radical through a rotation around the C_β – C_γ bond: the latter process could efficiently compete with β -fragmentation, thereby affecting the final alkene *E/Z* ratio (see Section 3.3).

We also exploited radical addition to isonitriles—coupled with the results obtained from our contemporaneous spectroscopic/kinetic investigation on the β -fragmentation of thioimidoyl radicals^{118,119}—as the key step for a novel tin-free procedure for alkyl radical generation.¹⁶⁷ As shown in Section 3.3, so fast is that fragmentation that practically every kind of alkyl radical, from stabilized radicals to even primary unstabilized alkyls, can be easily generated from 110 °C down to room temperature, simply by reacting the

Scheme 56 Tin-free alkyl radical generation by isonitrile-mediated thiol desulfuration.

corresponding alkanethiols with *tert*-butyl isonitrile in the presence of a radical initiator such as AIBN (80 or 110 °C) or triethylborane (room temperature). The ease of workup is the foremost feature of this reaction: indeed, the volatile by-product *tert*-butyl isothiocyanate can be simply evaporated off with the solvent, yielding reaction mixtures in which, on average, the products are already so pure as not to need further chromatographic purification. The methodology has been applied to defunctionalizations (including Barton–McCombie-type reactions on thiol sugars) and intermolecular additions of electrophilic radicals to electron-rich olefins (Scheme 56). In a radical chemistry domain still considerably monopolized by toxic tin reagents, this procedure aims at being an appealing substitute for many stannane-mediated radical reactions.

To our knowledge, the most up-to-date example of synthetic application of radical addition to isonitriles is the double chalcogenation reported by Ogawa *et al.* in 2007.¹⁶⁸ The photoinitiated reaction (tungsten lamp through Pyrex) between *aryl* isonitriles, disulfides, and diselenides selectively afforded thioselenation products in high yields. *Alkyl* isonitriles, under the same conditions, gave instead bithiolation products, but only in the concurrent presence of diselenide: in the absence of the latter no reaction was observed (Scheme 57).

The key intermediate is assumed to be a thioimidoyl radical derived from the addition of an arylsulfanyl radical to the isonitrile; subsequent

Scheme 57 Double radical chalcogenation of isonitriles.

intermolecular S_H2 reaction of the imidoyl with the dichalcogenides reagents gives, depending on the characteristics of the isonitrile, the bis-chalcogenated reaction products, which can be employed for the construction of β -lactam derivatives by formal [2 + 2] cycloaddition with ketene equivalents. Analogous reactions can be carried out between electron-deficient aryl isonitriles and a disulfide/ditelluride mixed system. In the presence of suitable unsaturated side chains, the intermediate imidoyl radicals arising from the addition of sulfanyl radicals to the isonitrile give rise to five- and six-membered bis-sulfanylated cyclization products (indoles and quinolines, respectively, Scheme 57).¹⁶⁹

4 HETEROCUMULENES

4.1 Introduction

Heterocumulenes are a group of molecules containing cumulative double bonds in which one or more carbon atoms are replaced by heteroatoms (Figure 3). The most common members include isocyanates ($XR^1 = N, Y = C, ZR^2$

$= O$), isothiocyanates ($XR^1 = N, Y = C, ZR^2 = S$), carbodiimides ($XR^1 = N, Y = C, Z = N$), ketenes ($X, Y = C, ZR^2 = O$), and ketenimines ($X, Y = C, Z = N$); even diazo compounds, through one of their resonance forms ($X = C, Y = N^+, ZR^2 = N^-$), can be included in this class of organic compounds.

The free-radical chemistry of heterocumulenes is very diverse, depending on the nature of the heteroatoms and their positions in the cumulative system. In principle, they behave like *vicinal* radical acceptor/radical donor synthons, affording either vinyl- or allyl-like radicals by addition to either a side (X, Z) or the central (Y) atom of the cumulene moiety, respectively.

However, examples related to some categories of heterocumulenes are extremely scarce. For instance, only two examples have been reported concerning radical addition to diazo compounds:^{170,171} in those papers, addition to the carbon atom (X atom of Figure 3) was claimed, but neither of them identified the actual radical intermediate, although Roberts *et al.*¹⁷¹ suggested that a diazenyl radical is probably involved. The net result of this kind of addition was a *geminal* radical acceptor/radical donor synthon behavior, since, after loss of molecular nitrogen, the radical was actually centered on the carbon atom that was the addition target.^{172,i}

Addition to carbodiimides is even more uncommon: the only example was reported in 1976 by Ingold *et al.*¹⁷³ who identified by EPR a 1,3-diazaallyl radical arising from addition of a trifluoromethoxyl to the central carbon atom (Y atom of Figure 3) of *N,N'*-di-*tert*-butylcarbodiimide. Interestingly, azaimidoyl radicals arising from addition to the side nitrogen atom of the symmetric cumulene were never detected, whereas, in the same paper, *N,N'*-di-*tert*-butylsulfurdiimide was found to afford nitrogen-centered radicals by addition to the side nitrogen instead of the central sulfur.

Radical addition to isocyanates is surprisingly sporadic as well. A few imidoyls generated by the addition of silyl radicals to the oxygen atom of isocyanates (Z atom of Figure 3) have been studied

Figure 3 Heterocumulenes: general formula.

by EPR spectroscopy (see also Section 3.3),^{106,114} whereas addition of muonium was found to occur at the nitrogen atom (X atom of Figure 3) to give a β -muoniated carbamoyl radical,^{172,174} although hydrogen atoms had been previously found to prefer to add to the central C atom.¹⁷⁵ Intramolecular 1,5- and 1,6-ring closures of carbon radicals onto *N*-acyl isocyanates were kinetically studied: very rapid cyclizations always occur onto the central C atom with formation of imidyl radicals.^{176–179,j} Kinetic and theoretical studies have been also carried out on cyclization of 2-(2-isocyanatophenyl)ethyl radical, generated from the corresponding bromide via tin- or silicon-centered radicals.¹⁸⁰ The reaction afforded indole and quinolinone derivatives through competitive, very fast 1,5- and 1,6-ring closures, with the latter strongly prevailing, especially in the presence of tris(trimethylsilyl)silane. This was explained by a reversible five-membered (onto nitrogen) cyclization competing with a substantially irreversible six-membered (onto carbon) ring closure, due to formation of a cyclic amidyl radical stabilized by resonance with the *N*-aromatic ring.

As far as we know, the actual synthetic procedures involving radical addition to isocyanates are almost totally missing, with the exception of a radical carbamoylation, appeared in 2007, where the triethylborane-mediated addition of α -aminoalkyl radicals to aromatic isocyanates yielded *N,N*-dialkylated aminoacid derivatives.¹⁸¹ It is worth emphasizing that, in this case, radical addition occurs exclusively at the central carbon atom of the isocyanate moiety, thus showing that isocyanates can react at all viable atoms, depending on the nature of the approaching radical species.

Isothiocyanates and ketene derivatives raised a more extensive interest and the next two sections deal with the results reported by radical additions to those classes of heterocumulenes.

4.2 Isothiocyanates

Compared to isonitriles, examples of synthetic applications of radical addition to isothiocyanates are much less plentiful. Accessibility of starting materials is certainly not a drawback: indeed, like isonitriles, isothiocyanates are easily accessible from the corresponding amines,

usually by reaction with either carbon disulfide/dicyclohexylcarbodiimide or (better) thiophosgene. Since all the reported examples, with the notable exception of muonium,¹⁷⁴ dealt with radical addition to the sulfur atom affording thioimidoyl radicals, it is likely that the number of achievable applications could be limited by the already mentioned fast C–S bond fragmentation of those thioimidoyls. In some cases, also α -scission of thioimidoyls affording isonitriles can become a competing, dangerous process, see: Refs 97–99.^{118,119,167} This process makes radical addition a reversible process in which the starting isothiocyanate is strongly favored, at least with usual alkyl radicals and at temperatures above 20 °C. Hence, useful synthetic procedures can only be designed either by means of suitable radicals that could bind to sulfur very tightly or in the presence of cyclizations (or other evolution routes) faster than back-fragmentation.

The pioneering work on synthetic applications of radical addition to isothiocyanates is once again one of Barton's papers,⁹⁷ where he used isothiocyanates (and isoselenocyanates as well) as intermediates for the stannane-mediated radical deamination of aminoglycosides.^{182,k} In this case, the strong tin–sulfur bond resulting by addition of tin radicals to the isothiocyanate prevents the retro-fragmentation, giving rise to a competitive α -scission of the thioimidoyl affording the corresponding isonitrile: attack of tin radicals to the latter gives a new imidoyl that eventually undergoes β -fragmentation of the C–N bond yielding the final deaminated product. Witczak observed that the intermediate isonitriles can also be obtained if the reaction of isothiocyanates with tributyltin hydride is carried out at low temperature and without a radical initiator,¹⁸³ whereas the occurrence of a radical mechanism is strictly required in order to reduce the isonitrile moiety.

On the other hand, Barton also discovered that alkyl radicals can trigger the transformation of sulfonyl isothiocyanates into alkyl thiocyanates: in this case, S–N β -fragmentation of the intermediate imidoyl with loss of sulfonyl radicals is so fast as to hinder S–C back-fragmentation, thus shifting the equilibrium of formation of the thioimidoyl radical (Scheme 58a).¹⁸⁴ We also observed a related behavior in the unusual multistep spirocyclization of an alkynylaryl isothiocyanate mediated by cyclohexyl radicals (Scheme 58b),¹⁴⁴ in which a very

(a) (X = Ts, MeSO₂, R = *c*-C₆H₁₁, PhCH₂CH₂)

Scheme 58 Radical reactions of isothiocyanates mediated by alkyl radicals.

fast cyclization sequence overcomes the unfavorable fragmentation equilibrium of the intermediate thioimidoyl.

The alternative practice of circumventing the *S*-side fragmentation of thioimidoyls through formation of strong S–Sn bonds was exploited by John, Thomas, *et al.*¹⁸⁵ in the tin-radical-mediated isomerization of 6β-isothiocyanatopenicillanate and, above all, by Bachi *et al.*^{98,149,151} who used tin radical addition to isothiocyanates to perform cyclizations analogous to those previously reported for unsaturated isonitriles (Scheme 51). Accordingly, alk-3-enyl and alk-4-enyl isothiocyanates gave good yields of γ- and δ-thiolactams when treated with tributyltin hydride/AIBN at 75 °C (Scheme 59).⁹⁸ The reaction exhibited good stereocontrol with suitably substituted substrates (*n* = 1, R¹ = R² = Me, R³ = H, R⁴ = OTBDMS, R⁵ = CO₂Et), similar to that obtained with analogous isonitriles,¹⁴⁹ and was also applied as a route for the stereoselective synthesis of (±)-α-kainic acid.¹⁵¹

A further method for carrying out radical addition to isothiocyanates avoiding *S*-side back-fragmentation of the intermediate thioimidoyls entails the reaction with aryl radicals, which give

Scheme 59 Radical reactions of alkenyl isothiocyanates mediated by tin radicals.

rise to a substantially irreversible addition with formation of strong *S*-aryl bond. This methodology allowed the accomplishment of tandem cyclizations leading to heterocyclic systems, as shown in the reactions of aryl isothiocyanates with 2-cyano-⁹⁹ and 2-alkynyl-substituted aryl radicals¹⁸⁶ and in those of 2-alkynylaryl isothiocyanates with simple aryl radicals.¹⁸⁷

Aryl radicals were generated by decomposition of the corresponding diazonium tetrafluoroborates with either pyridine at –10 to –20 °C or ethyl acetate/potassium acetate/[18-crown-6] at room temperature, and were reacted with a series of aryl isothiocyanates to give benzothieno-quinoxalines (X = N) or -quinolines (X = PhC) (Scheme 60a). The mechanism entails the formation of thioimidoyl radicals, followed by 5-exo cyclization onto the cyano group (a rare example of [3 + 2] radical annulation) or the alkynyl moiety, and eventual cyclization of the resulting iminyl (X = N) or vinyl (X = PhC) radicals. In the latter case, mixtures of isomeric benzothienoquinolines were obtained, as the result of competitive five- and six-membered aromatic ring closure of the intermediate vinyl radicals. The isomer ratio was found to be dependent on the nature of the *Z*-substituent: the better the electron-withdrawing capability of *Z*, the higher the preference observed for the “rearranged” isomer, probably as a result of a SOMO/LUMO controlled cyclization of the slightly nucleophilic vinyl radical. The authors also found evidence that the attack of the aryl radical on the isothiocyanate is somewhat affected by polar factors: substituents that increase the electrophilicity of the aryl radical seem to favor addition to the substantially nucleophilic sulfur atom of the isothiocyanate, thereby increasing the overall efficiency of the cascade reaction.

The analogous reaction of aryl radicals with 2-alkynylaryl isothiocyanate gave mixtures of isomeric thiochromenoindoles through competitive [4 + 2] and [4 + 1] annulations. In this case, the

Scheme 60 Radical annulations of isothiocyanates with aryl radicals.

isomer ratio was found to be strictly correlated to the ability of the Y substituent to delocalize spin density and seems therefore the result of thermodynamic rather than kinetic control (Scheme 60b).

4.3 Ketenes and Ketenimines

References to free-radical reactions of ketenes are pretty scattered but more numerous than one would expect. Examples include reactions with peroxy radicals (as well as $^3\text{O}_2$), hydrogen atoms, fluorinated carbon radicals, alkoxy (and hydroxyls), halogen atoms, and carbon-centered radicals.¹⁸⁸ Most of the work has been carried out

in the first decade of the new century by Tidwell *et al.*,^{188–197} who focused their attention on the regiochemistry of radical addition, which actually had been found to depend on the nature of both the ketene substituents and the attacking radical.^{198–200} In a theoretical study,¹⁸⁸ for example, they found that radicals containing lone pairs (e.g., $\cdot\text{OH}$, $\cdot\text{F}$, and $\cdot\text{Cl}$) preferentially attack C_α , owing to the stabilization arising from conjugation between the carbonyl group and the lone pairs; on the contrary, H atoms and silyl radicals ($\cdot\text{SiH}_3$) add to C_β (the latter as a result of hyperconjugative effects), whereas carbon radicals give rise to competitive C_α and C_β additions (Scheme 61).

Contrary to other lone-pair-containing radicals, which were predicted to give exothermic additions to both C_α and C_β , with the former however more favored, aminoxyls ($\cdot\text{ONH}_2$) were expected to show a more marked regioselectivity, because of an endothermic C_β -addition coupled with a competitive exothermic C_α -addition.¹⁸⁹ This opened the door to a thorough preparative, kinetic, and theoretical study on the addition of nitroxyls (namely TEMPO) to a wide range of ketenes:^{189–197} in all cases, regioselective addition to C_α afforded enolic radicals whose fate (trapping by a second TEMPO or dioxygen, rearrangements, cyclizations, etc.) depended on the type of ketene employed and the experimental conditions. In general, the reactivity is dominated by the nucleophilic character of the aminoxyl oxygen, which reacts more easily by increasing the electrophilicity of the ketene.

Amazingly, the only synthetic procedures reported so far concerning radical addition to ketenes do not really involve ketenes! Indeed, the nice work carried out by Pattenden *et al.*

Scheme 61 Regiochemistry in radical addition to ketene.

Scheme 62 Generation and cyclization of α -ketenyl alkyl radicals.

in a decade around the end of the last century exploited cascade cyclizations of α,β -unsaturated acyl radicals, which reacted via their α -ketenyl alkyl radical equivalents by employing starting materials that actually did not contain at all ketene moieties.^{122,123,201–207} The results obtained were in fact explained in terms of the reactivity of the rearranged (and mesomeric) α -ketenyl alkyl radical form **47** of the initially generated β,γ -unsaturated acyl radical **46** (Scheme 62). The intermediacy of radicals **47** was initially suggested by the evidence of *E/Z* isomerization of the unsaturated acyl radicals²⁰¹ (a phenomenon analogous to that discussed above for imidoyls, see Scheme 44)¹²¹ and was exploited for tandem cyclizations leading to the synthesis of assorted cyclic and polycyclic compounds, including diquinanes^{201,203,205,206} and

Scheme 63 Cyclization of *o*-ketenimino-substituted benzylic radicals.

triquinanes.^{123,204,207} In all cases, only ring-closure onto the C_α atom was observed to give an enolic radical. The methodology was also applied to cyclopropane-substituted acyl radical precursors **48**, which can generate the same α -ketenyl radicals by ring-opening of intermediate cyclopropyl acyl radicals.^{122,201,202,205,206}

As far as ketenimines are concerned, this radical trap has remained totally unexplored since 2003, when Vidal *et al.* investigated cyclization of *o*-ketenimino-substituted benzylic radicals as a route to 2-alkylindoles.^{208–210} The protocol entailed a non-chain reaction between suitable xanthates and peroxides, with ring-closure of the intermediate benzylic radical onto the central carbon atom of the ketenimine moiety to afford an aza enolic radical analogous to that generated by C_α -attack on ketenes (Scheme 63). Interestingly, analogous cyclizations onto either *o*-carbodiimido or *o*-isothiocyanato moieties failed: see Ref. 209.

The protocol was extended to generation of benzylic and aryloxymethyl radicals from benzyl phenyl selenides²¹¹ and (phenylseleno)methyl aryl ethers,²¹² respectively, by treatment of the precursors with tris(trimethylsilyl)silane/AIBN: in the latter case, 2*H*-1,4-benzoxazines were obtained.²¹³

5 CONCLUSION

This review should have shown that the word “unusual” does not necessarily means “exotic” or “weird”! On the contrary, the “unusual” radical traps described in this article are very useful radical acceptors that, in most cases, are readily accessible

and allow the generation of very appealing intermediates and the consequent synthesis of an extensive assortment of compounds. Azides, in particular, should not be considered any more as hazardous chemicals, but instead as easy-to-make, attractive, and extraordinarily versatile compounds that can open the door to very convenient routes to both cyclic and acyclic nitrogen compounds through the intermediacy of a variety of nitrogen-centered radicals (triazenyl, aminyl, and even iminyl). Likewise, reactions involving isonitriles are not anymore a mere academic pastime but, on the contrary, via generation of imidoyl radicals, they represent a nice route to assorted nitrogen heterocycles and other remarkable derivatives, often through multicomponent procedures. Even the more unusual heterocumulenes are showing their potential in free-radical-mediated organic synthesis, especially as a route to cyclic and polycyclic compounds. The employment of the above moieties as radical acceptors in organic synthesis is certainly far from being close to an end, showing once more that radical reactions can be applied to a really huge range of substrates and are definitely one of the most widespread tools in organic chemists' hands.

END NOTES

^a. Although imidoyl radicals are *bona fide* intermediates in many examples of radical addition to isonitriles—as demonstrated by EPR spectroscopy—Kim has suggested that a concerted process, occurring through a polar transition state, could be involved in the isonitrile/nitrile isomerization when a particular stable radical, such as benzyl, can be released by β -fragmentation. This has been proposed for addition of phenyl and tributyltin radicals to benzyl isonitrile; see Ref. 84.

^b. An additional α -fragmentation of the imidoyl (Me_3Si) $\text{N}=\text{C}^*(\text{tert-Bu})$ to give Me_3SiNC and *tert*-Bu radical has been proposed by Ingold to explain the radicals detected in the addition of trimethylsilyl radicals to pivalonitrile; see Ref. 100.

^c. For an additional EPR study on radicals generated from imines; see Ref. 103, although in this paper detection of imidoyls was hindered by competing addition of *tert*-butoxy radicals to the parent imines, giving aminyls and nitroxides.

^d. Imidoyl radicals could also be formed by Group 11 metal atoms addition to isonitriles in a rotating

cryostat at 77 K. However, if ever formed, under those conditions they seem extremely prone to fragmentation and could not be observed even at so low temperatures; see Ref. 117.

^e. A cyanide transfer has been also observed between butyl isonitrile and the metalloradical rhodium(II) tetramesitylporphyrin. In that case, however, the reported kinetics suggest a more complicated mechanism compared to the usual radical addition/fragmentation pathway normally observed with organic radicals; see Ref. 130.

^f. The possibility of one-electron-transfer reduction of isonitriles to the corresponding radical anions has been suggested to occur in cyclizations of *o*-isocyano- β,β -difluorostyrenes mediated by *n*- Bu_3SnLi , which afforded, as major products, either 3-fluoroquinolines or 3,3'-difluoro-2,2'-biquinolines, depending on the order of addition of the reagents; see Ref. 145.

^g. For another example of attack on aromatic rings of imidoyl radicals generated from isonitriles, see Ref. 146. In that case, 2-(phenoxy)phenyl isonitrile, when treated with dibenzoyl peroxide, gave 2-phenyloxazole through presumable 1,5-phenyl radical migration followed by ring closure of the resulting phenoxyl with expulsion of benzoyloxy radicals.

^h. Another convenient enantioselective total synthesis of (–)- α -kainic acid was achieved by tin radical addition to an alkenyl thioformamide; see Ref. 153. Similar cyclizations to thiolactams were also carried out by tin radical additions to alkenyl isothiocyanates; see Ref. 98.

ⁱ. For addition of muonium to diazo-compounds giving α -muoniated alkyl radicals, see Ref. 172. In this paper also a stable carbene (1,3,4-triphenyl-4,5-dihydro-1,2,4-triazol-5-ylidene) was used as a trap for muonium.

^j. An intramolecular ring closure of biphenyl-2-yl isocyanate to carbazole and phenanthridone under photolytic conditions has been also reported; see Ref. 179. It is, however, unclear whether this reaction actually involves a free radical mechanism.

^k. There are actually a couple of previous papers, which date back to the beginning of the 1960s, that report some reactions of isocyanates and isothiocyanates with organostannanes; see Ref. 182a,b. Nevertheless, in those papers no evidence is reported about the intermediacy of radical species. See also Ref. 182c.

Nitroxides in Synthetic Radical Chemistry

Chittreya Tansakul and Rebecca Braslau

Department of Chemistry and Biochemistry, University of California Santa Cruz, Santa Cruz, CA, USA

1 INTRODUCTION

Nitroxides (NitO•) are kinetically persistent organic free radicals. Many are stable, commercially available compounds, and can be handled in the laboratory without any special requirements. The most commonly utilized nitroxide in synthesis is 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO). Nitroxides efficiently trap carbon radicals and are easily reduced to the corresponding hydroxylamines or oxidized to oxoammonium cations (Scheme 1). Synthetically, nitroxides have found utility as stoichiometric radical traps, often following radical cyclization processes. Nitroxides are also excellent mediators of redox processes, providing chemoselective methods for the oxidation of alcohols, often using very inexpensive ultimate oxidants such as oxygen from air, bleach, or peroxides. Nitroxides are used as mild, environmentally benign primary oxidants for transition metal catalyzed processes. Electron poor nitroxides abstract activated hydrogen atoms, and add to olefins, providing additional modes of reactivity. This article will outline the wide range of uses of nitroxides in synthesis, focusing on recent developments. A number of excellent reviews are available which highlight the state-of-the-art work at the time they were written.^{1–10}

2 NITROXIDES AS CARBON RADICAL TRAPS

2.1 Direct Trapping of Carbon Radicals

Nitroxides trap carbon radicals at near-diffusion rate constants,^{11–13} converting organic radicals to alkoxyamines. As this is a radical-terminating event, this type of trapping cannot be utilized to perpetuate radical chain reactions. Nitroxide trapping has been used extensively as mechanistic probes¹⁴ for carbon radical intermediates and to calibrate the rate constants of radical rearrangements; however, these applications will not be covered here. In addition, the trapping of carbon radicals by addition to nitrene or nitroso species to form nitroxides, detected by EPR (“spin trapping”),¹⁵ is beyond the scope of this article (see **Spin Labels and Spin Probes**).

Nitroxides react with a variety of organometallic agents such as Grignard reagents; typically, 1 equiv of nitroxide affects oxidation of the organic moiety to the corresponding radical, which is then trapped by a second equivalent of nitroxide (Scheme 2).^{16,17} In an early example by Dalko,¹⁸ organolithiums bearing a chiral auxiliary trapped TEMPO with good diastereoselectivity. Fensterbank and coworkers have recently developed the generation of carbon radicals from alkyltrifluoroborates by addition of 1 equiv of a strong oxidant (either Cu(II) or

Scheme 1 Three main reactions of dialkyl nitroxides: reduction, oxidation, and trapping carbon radicals.

Scheme 2 Reaction of nitroxide with Grignard and other organometallic reagents.

Scheme 3 Generation of a carbon radical from an alkyltrifluoroborate; trapping with nitroxide.

Dess–Martin periodinane); TEMPO trapping forms the alkoxyamines¹⁹ (Scheme 3).

Using these conditions, nitroxide trapping is faster than 5-*exo*-trig cyclization; however, cyclopropylcarbinyl ring opening is even faster, giving only the ring-opened cyclohexene product (Scheme 4).

Alkoxyamines have found extensive use as initiators for nitroxide-mediated radical polymerization (NMRP) (see **Nitroxide-Mediated Polymerization**

Scheme 4 Cyclopropylcarbinyl ring opening is faster than nitroxide trapping.

Scheme 5 Alkoxyamine synthesis via addition of an electron-rich olefin to an oxoammonium cation.

and its Applications). Numerous methodologies have been developed to prepare alkoxyamines for this purpose.^{20–26} The preparation of alkoxyamines to form NMRP initiators has been recently reviewed⁵ and has not been repeated here. However, one unusual mode of reactivity will be highlighted, in which nucleophilic addition of an electron-rich olefin to the oxygen of an oxoammonium cation forms the key carbon–oxygen bond.²⁷ For example, Church *et al.*²⁸ have created alkoxyamine nucleoside analogs by reaction of dihydrofuran with an oxoammonium salt in the presence of a silylated thymine (Scheme 5).

The trapping of carbon radicals by nitroxides for synthetic purposes has been utilized as a chemoselective method to introduce oxygen into complex molecules. For example, photolysis of a neopentyl alkyl iodide in the presence of TEMPO followed by reductive O–N bond cleavage with sodium-ammonia provided a hydroxyl group in the synthesis of sucrose (Scheme 6).²⁹ Attempts to use oxygen nucleophiles to introduce the hydroxyl group at this position failed due to steric hindrance.

Scheme 6 Trapping of a neopentyl carbon radical by TEMPO to install a hydroxy group at a very sterically hindered position.

Scheme 7 Generation of a carbon radical by nitroxide addition to an alkylcatecholborane.

2.2 Nitroxide Addition to Catecholboranes

Schaffner and Renaud³⁰ have developed a very mild methodology using catecholboranes as a convenient sources of alkyl radicals (see **Boron in Radical Chemistry**), which can undergo radical rearrangement or rapid olefin addition reactions before being trapped by nitroxides. This protocol is based on the facile addition of oxygen radicals, including nitroxides, to alkylcatecholboronates to form stabilized perboryl intermediates, which fragment by release of alkyl radicals (Scheme 7).

Since nitroxides couple with alkyl radicals very quickly, olefin addition is successful only with highly activated radical traps. As a collaboration between Renaud and Studer, catecholboron enolates were shown to react with TEMPO to give α -keto alkoxyamines (Scheme 8).³¹

Wagner and Studer³² have applied this direct radical trapping with functionalized nitroxides to “decorate” polymers and dendrimers bearing accessible terminal olefins (Scheme 9) with a variety groups,

such as fluorescent tags, solubilizing poly(ethylene glycol) (PEG) groups, a protected sugar, and terminal alkynes for “click” functionalization.

2.3 α -Oxyamination of Enamines

Enamines are easily oxidized to radical cations, which can be trapped by TEMPO. Schamann and

Scheme 8 Reaction of a catecholboron enolate with TEMPO to form an α -keto alkoxyamine.

Scheme 9 Hydroboration, radical generation protocol to decorate macromolecules bearing terminal alkenes with nitroxides bearing useful functionality.

Schafer investigated anodic oxidation of TEMPO to form the oxoammonium salt in the presence of enamine to give the α -alkoxyamine.³³ The mechanism is either electron transfer to form the radical cation (“SOMO catalysis,” see **Synthetic Radical Photochemistry**) and the nitroxide, followed by heterocoupling, or electrophilic addition of the oxoammonium cation to the enamine (Scheme 10).

The mechanistic pathway is determined by the ease of oxidation of the nitroxide versus the enamine. Sibi and Hasegawa³⁴ extended this reaction using optically active amines as organocatalysts and Fe(III) (generated catalytically from NaNO₂ and O₂) as the oxidant to carry out enantioselective

α -alkoxyamination of aldehydes (Scheme 11) (see **Stereoselective Radical Reactions**). The resulting aldehyde can undergo epimerization, thus reduction to the alcohol was carried out to provide a stable product. A number of variations in this procedure include work using anodic oxidation³⁵ or benzoyl peroxide³⁶ as the oxidant. Use of a proline-terminated peptide on a solid support as the organocatalyst was reported by Kudo and coworkers.³⁷ A recent mechanistic investigation by MacMillan and coworkers,³⁸ based on kinetic studies, calculations, and use of a cyclopropyl carbinyl “radical clock” to probe for a free radical intermediate, suggests that many of these reactions occur through an electrophilic metal-activated TEMPO species reacting with an enamine nucleophile. Variation of the reaction conditions, including the choice of metal (Fe, Cu, etc.), ligands, and solvent shifts the reaction mechanism between electrophilic addition and radical character. An interesting use of a photoexcited Ru(II) catalyst³⁹ as the oxidant in a racemic α -oxyamination reaction may also be going through a metal-activated TEMPO electrophile rather than the reported enamine radical cation intermediate. The use of photocatalyzed Rose Bengal with 1,3-dicarbonyl compounds and TEMPO results in α -alkoxyamination,⁴⁰ presumably via single electron transfer (SET) of the enolate followed by nitroxide trapping.

Scheme 10 Two mechanistic pathways for the α -oxyamination of enamines with TEMPO.

Scheme 11 Organocatalytic asymmetric α -oxyamination of enamines with TEMPO via an electrophilic metal-activated nitroxide complex.

2.4 Cyclization Followed by Nitroxide Trapping of Carbon Radical

The development of synthetic radical sequences that incorporate formation of a covalent carbon–carbon bond before nitroxide trapping are not very numerous, as premature trapping of the initial radical by nitroxide must be avoided. Thus, very fast carbon–carbon bond forming reactions must be employed before nitroxide trapping to ensure success. Often fast unimolecular rates of

cyclizations can be used to successfully orchestrate conditions to allow useful covalent bond construction before termination by nitroxide trapping.

Tributyltin hydride-mediated radical formation followed by TEMPO trapping, with or without cyclization, was demonstrated by Bergman and coworkers in 1978.⁴¹ On the basis of this, an efficient synthesis of 3-(hydroxymethyl)indolines, using a radical cyclization, TEMPO trapping sequence was utilized by Boger and McKie⁴² in the synthesis of CC-1065 analogues (Scheme 12).

Scheme 12 Boger's radical 5-*exo*-trig cyclization followed by nitroxide trapping in the synthesis of CC-1065 analogues.

Scheme 13 Jahn's oxidation of an anion to radical, 5-*exo*-trig cyclization, and nitroxide trapping sequence in the synthesis of an isoprostane metabolite.

Extending the efficiency of radical tandem reactions to include a redox step, Jahn *et al.*⁴³ have developed an anionic Michael addition, radical cyclization, and nitroxide trapping sequence utilizing ferrocenium ion for enolate oxidation to a carbon radical. A recent variation of this chemistry toward the synthesis of isoprostane metabolites demonstrated diastereoreversibility by varying the enolate counterion between lithium (open TS) and magnesium (chelated TS).⁴⁴ For example, use of LDA gave predominately the diastereomer and regioisomer shown; the alkoxyamine–TEMPO

moiety was oxidatively converted to the ketone using *m*CPBA⁴⁵ (Scheme 13).

In a related ionic/radical domino reaction, Fensterbank and Malacria have utilized optically active alkylidene bis-sulfoxides in a Michael addition, radical cyclization protocol.⁴⁶ For example, Michael addition of the lithium anion of allyl alcohol gave the bis-sulfoxide-stabilized anion, which was oxidized to the radical, followed by 5-*exo*-trig radical cyclization and nitroxide trapping to give a single optically active diastereomer (Scheme 14).

Scheme 14 Fensterbank and Malacria's Michael addition, oxidation to radical, 5-*exo*-trig cyclization, and nitroxide trapping protocol with an optically active bis-sulfoxide.

Scheme 15 Fensterbank and Malacria's Michael addition, oxidation to radical, reversible 3-*exo*-trig cyclization, and nitroxide trapping protocol with an optically active bis-sulfoxide.

Scheme 16 Braslau's acyl radical 5-*exo*-trig cyclization and nitroxide trapping and elimination protocol.

This methodology was extended to the formation of a cyclopropyl ring using a reversible 3-*exo*-trig cyclization; as a demonstration of synthetic utility, the sulfoxides were reductively removed in excellent yield (Scheme 15).

In our own laboratory, oxidative formation of acyl radicals in the presence of nitroxides was utilized to effect a cyclization, nitroxide trapping sequence.⁴⁷ The alkoxyamine product was thermolyzed in the presence of acidic silica gel to afford the α,β -unsaturated ketone, the ionic elimination product (Scheme 16).

Chemler⁴⁸ has recently developed an intramolecular aminocupration, TEMPO trapping protocol in which the nitroxide acts as both a stoichiometric oxidant, converting the Cu(I) byproduct to the active Cu(II) catalyst, and as the final radical trap. Use of the optically active ligand (*R,R*)-Ph-Box (L*) provided highly enantioenriched alkoxyamines (Scheme 17).

Enediyne take part in Bergman cyclizations to form 1,4-benzene diradicals, which have been trapped by TEMPO by Grissom and Gunawardena.⁴⁹ The bis-alkoxyamine underwent homolysis

Scheme 17 Chemler's intramolecular aminocupration and TEMPO trapping protocol using TEMPO as both an oxidant of Cu(I) and the final radical trap.

under the reaction conditions (heating to 160 °C) to yield the quinone (Scheme 18).

2.5 Carbon Radical Addition to Olefin Followed by Nitroxide Trapping

Aryl radicals have been generated by iron-mediated decomposition of diazonium salts in the presence of olefins and TEMPO. Heinrich *et al.*⁵⁰ found that by employing aqueous DMSO as a

Scheme 18 Grissom's Bergman cyclization of an enediyne; trapping of the 1,4-benzene diradical by TEMPO and fragmentation to the quinone.

Scheme 19 Heinrich *et al.*'s oxidative aryl radical generation, addition to an electron-rich olefin, and nitroxide trapping sequence.

polar hydrogen-bonding solvent (which reduces the carbon-trapping rate of the nitroxide¹¹), aryl radical addition to olefins followed by nitroxide trapping could be achieved in moderate to very good yields (Scheme 19). The choice of solvent was critical:

both activated and unactivated olefins could be utilized, without formation of the arylalkoxyamine direct trapping product.

3 HOMOLYSIS OF ALKOXYAMINES

On the basis of the persistent radical effect⁵¹ behind nitroxide-mediated polymerization (see **Nitroxide-Mediated Polymerization and its Applications**), a properly designed alkoxyamine can undergo reversible bond homolysis to give a stabilized carbon radical and nitroxide. As this is a degenerate reaction,⁵² addition of the stabilized carbon radical to olefin radical acceptors can be accomplished with even unactivated olefin traps, resulting in

Scheme 20 Both Studer and Ciufolini pioneered homolysis of an alkoxyamine followed by cyclization and nitroxide trapping.

Scheme 21 Studer has employed the reversible homolysis of malonylalkoxyamines to functionalize the outer surface of self-assembled monolayers.

the formation of a carbon–carbon bond and a new alkoxyamine. Initial work by the groups of Studer⁵³ and Ciufolini⁵⁴ demonstrated both inter- and intramolecular radical additions (Scheme 20), and utilized a variety of nitroxides, focusing mainly on TEMPO and SG1, respectively.

Studer and coworkers developed malonyl⁵⁵ as the stabilized radical partner as well as 1,3-dithiane⁵⁶ as a 1-carbon radical synthon for this process. The use of microwave⁵⁷ and more recently microflow⁵⁸ reactors have been investigated to optimize the efficiency of this process. A number of synthetic applications include intramolecular cyclization of ester-stabilized radicals to form lactones,⁵⁹ addition of the carbon radical to carbon monoxide,⁶⁰ isonitriles,⁶¹ and a sequential radical addition with malonyl radical, followed by a Pd catalyzed π -allyl cyclization.⁶² The electron-poor malonyl radical adds well to electron-rich unactivated olefins; this method has been recently utilized to functionalize

the outer surface of self-assembled monolayers bearing terminal alkenes⁶³ (Scheme 21). Alkoxyamines based on SG1 have been added by homolytic thermolysis to tri- and tetra-acrylates to form initiators for 3 and 4-armed star polymers.⁶⁴

4 ADDITION OF NITROXIDES TO UNSATURATION

Dialkyl nitroxides (such as TEMPO) do not add to olefins or alkynes, nor do they abstract hydrogen atoms under ambient conditions (although both reactions are observed at elevated temperatures⁶⁵). In contrast, electron-poor nitroxides, such as Fremy's salt ((KO₃S)NO[•]), acyl nitroxides, and diacyl nitroxides (such as phthalimide *N*-oxyl (PINO)), are far less stable than TEMPO and related nitroxides and undergo both hydrogen atom abstraction and addition to unsaturation (*vide infra*). Taking advantage

Scheme 22 Alexanian's acyl radical cyclization and oxygen trapping as a metal-free dioxygenation protocol.

Scheme 23 Tidwell's bisaddition of nitroxide to ketene.

of an acyl radical cyclization on a pendant olefin first described by Perkins and coworkers,⁶⁶ Schmidt and Alexanian⁶⁷ have recently utilized this reaction followed by trapping with molecular oxygen as a “metal-free dioxygenation” protocol for alkenes (Scheme 22). An analogous oxidative acyl radical cyclization on an allene has been reported.⁶⁸

TEMPO does add to ketenes: the scope⁶⁹ and kinetics⁷⁰ have been studied by Tidwell and coworkers (Scheme 23). Addition of the nitroxide to the carbonyl-like carbon generates an ester-stabilized radical, which is trapped by a second nitroxide. In the presence of a pendant olefin, thermolytic homolysis as a subsequent step leads to 5-*exo*-trig cyclization (Scheme 24).

5 NITROXIDES AS OXIDANTS

Oxidations using nitroxides are remarkably mild and chemoselective. Isomerizations of double bonds and stereogenic centers are rarely observed. Moreover, no heavy metals such as chromium or manganese are required. As a result, nitroxide-mediated oxidations are considered “green.” Nitroxide radicals, especially TEMPO and derivatives, are easily converted to the corresponding oxoammonium cations, which are highly reactive oxidants. In addition to alcohol oxidations, oxoammonium species are

utilized as one-electron oxidants with a variety of substrates, including sulfides, thiols, phenols, and activated alkenes. Oxidations mediated by electron-poor nitroxides occur via hydrogen abstraction. Nitroxide-mediated oxidations have been covered in a number of reviews.^{71–80}

5.1 Nitroxide as a SET Oxidant

Nitroxides are easily oxidized to the corresponding oxoammonium ion, or reduced to the corresponding hydroxylamine anion, many in a reversible manner. The redox potentials for a range of nitroxides have been studied both experimentally and predicted by calculations.⁸¹ Thus, nitroxides, and TEMPO in particular, have been utilized as environmental-friendly one-electron oxidants in a variety of reactions. In some cases, the nitroxide can be utilized catalytically, with O₂ (ideally from air) being the ultimate oxidant.

5.1.1 Nitroxide as a SET Oxidant of Organic Species

As chemists seek to avoid the use of metal catalysts for both environmental and economic reasons, alternative catalysts are being sought. Recently, chemists have found that TEMPO acts as an organic soluble single electron oxidant. For example, Han and coworkers have utilized 5% of 4-methoxy TEMPO and molecular oxygen to aromatize aminols to form benzoxazoles (Scheme 25).⁸² The mechanism most likely goes through a radical cation, which is further

Scheme 24 Alkoxyamine homolysis and cyclization of Tidwell's ketene plus nitroxides adduct.

Scheme 25 Han's aerobic nitroxide-catalyzed aromatization of a benzylic aminol to form a benzoxazole.

Scheme 26 Studer's stoichiometric use of TEMPO in the homocoupling of vinyl and aryl Grignards.

oxidized by TEMPO or oxygen to the aromatic system. An alternative mechanism involves 5-*endo*-trig cyclization of a phenoxy radical, followed by oxidative aromatization. Studer and coworkers have utilized TEMPO in the oxidative homocoupling of vinyl and aryl Grignards (Scheme 26).⁸³ The mechanism does not seem to go through a free radical intermediate, as no 5-*exo*-trig cyclization was seen with an *ortho*-allyloxy probe (Scheme 27). Alkynyl Grignards also work but do not require the nitroxide catalyst: air is sufficient. This methodology has been extended to the preparation of conjugated polymers such as polyfluorenes using symmetrical bis-bromofluorenes via the bis-Grignards.⁸⁴

TEMPO has been employed as a double oxidant in a catalytic *N*-heterocyclic carbene oxidation of aldehydes to carboxylic acid derivatives (Scheme 28).⁸⁵ Condensation of the carbene with aryl or vinyl aldehyde forms a very electron-rich enol/enamine (Breslow intermediate); SET by the nitroxide gives a radical cation. Another SET reaction (or nitroxide trapping followed by ionic elimination) forms an activated cationic leaving group on the carbonyl. Displacement by the hydroxylamine anion (the reduced TEMPO) yields the ester in excellent yields. Use of alkyl aldehydes affects oxidation in moderate yields. This process is biomimetic, emulating the steps involved in pyruvate ferredoxin oxidoreductase in the oxidative decarboxylation of pyruvate, in which an [Fe₄S₄] cluster is the biological SET agent. More recently, TEMPO has been replaced by diphenoquinone as the oxidant (the reduction product is nonnucleophilic), allowing addition of exogenous nitrogen nucleophiles to trap the activated acyl intermediate.⁸⁶

TEMPO has been utilized to oxidize Hantzsch 1,4-dihydropyridines (an NADH analogue) in a photochemical process (Scheme 29)⁸⁷; the exact role of the UV light was not illuminated. Two equivalents of TEMPO per dihydropyridine were required for aromatization. A photoinduced electron transfer mechanism was proposed; however, hydride addition to an oxoammonium ion was not ruled out. Alternatively, hydrogen abstraction by a photoexcited nitroxide is a possible first step.

Preformed oxoammonium salts have been employed as well-behaved organic soluble oxidants to convert electron-rich tetrathiafulvalene to the radical cation.⁸⁸ A series of bis-1,3-dithiolium salts,

Scheme 27 Evidence against a radical intermediate in the TEMPO-mediated homocoupling of aryl Grignard.

Scheme 29 TEMPO as oxidant in the photochemical aromatization of a Hantzsch 1,4-dihydropyridine.

with potential applications as semiconductors, were isolated in high yields.

5.1.2 Nitroxide as an Oxidant of Metal Catalysts and Metal Complexes

Nitroxides have been utilized as a reoxidant of the transition metal catalysts palladium and rhodium. Several homocouplings of aryl or vinyl boronic acids have been reported. Vogler and Studer⁸⁹ utilized TEMPO as a stoichiometric reoxidant to

convert Rh(I) to Rh(III) in the homocoupling of both aryl and vinylboronic acids, in moderate to very good yields (Scheme 30).

Mitsudo *et al.*⁹⁰ have successfully developed a similar palladium catalyzed reaction, in which both the metal and nitroxide are used catalytically using electrochemistry as the ultimate oxidant (Scheme 31). In this catalytic cycle, the active Pd(II) catalyst undergoes transmetalation twice with arylboronates to give Ar-Pd-Ar, which undergoes reductive elimination to form the biaryl product and Pd(0). An oxoammonium cation reoxidizes the Pd(0) to Pd(II), forming nitroxide, which is then oxidized at the anode back to oxoammonium ion. Another example of homocoupling, in this instance using an imidazoline nitroxide as the oxidant, is the formation of a symmetrical diyne in the presence of a palladium catalyst (Scheme 32).⁹¹ Presumably, Pd(0) inserts into the terminal acetylene C–H bond; however, the detailed mechanism is not clear. No reaction proceeded in the absence of the palladium catalyst.

Scheme 30 TEMPO as a stoichiometric reoxidant of Rh(I) to Rh(III) in the Rh-catalyzed homocoupling of an arylboronic acid.

Scheme 31 Anodic oxidation of TEMPO as a cooxidant in the Pd-catalyzed homocoupling of an arylboronic acid.

Scheme 32 An imidazoline nitroxide as the oxidant in the Pd-catalyzed homocoupling of a terminal alkyne.

Using TEMPO as a stoichiometric oxidant, Studer and coworkers have demonstrated directed orthometallation using Pd⁹² or Rh⁹³ catalysts with 2-pyridyl aromatics (and heteroaromatics) and arylboronic acids (Scheme 33). Although the mechanism of C–H activation is not understood, despite several kinetic isotope experiments, one possible mechanism is illustrated here. Regardless of the mechanism of C–H insertion step, it is clear that the nitroxide acts as an oxidant to reoxidize Pd(0) to the active Pd(II) catalyst. The Rh catalyzed case is analogous. In another reaction using an indene substrate, a palladium catalyzed oxyarylation was observed with arylboronic acids and TEMPO (Scheme 34).⁹⁴

Only a single diastereomer was formed in this very acidic medium. The mechanism is not clear: a Heck-like addition was disfavored compared to electrophilic attack of the indene on an aryl palladium salt. Whatever the actual mechanism, the nitroxide is both a reagent in the reaction and is the stoichiometric oxidant, converting Pd(0) to the active Pd(II) catalyst. Several 4-substituted TEMPO derivatives were utilized in addition to the parent TEMPO nitroxide.

In an example of a copper-catalyzed process, Lam *et al.*⁹⁵ have used TEMPO as a stoichiometric oxidant in the *N*-arylation of anilines, carbamates, imides, sulfonamides, and amines as well as

Scheme 33 TEMPO as a superstoichiometric reoxidant of Pd(0) to Pd(II) in a Pd-catalyzed orthometallation, heterocoupling sequence with an arylboronic acid.

O-arylation of phenols in a cross-coupling reaction with the arylboronic acids (Scheme 35). Vinylation was also successful.

TEMPO has also been used as a mild oxidant for metals. In the Pauson–Khand reaction, the addition of superstoichiometric amounts of TEMPO was found to greatly accelerate the rates and enhance the yields of the Pauson–Khand reaction of dicobalt acetylenes with norbornadiene.⁹⁶ Calculations indicate that the nitroxide promoter facilitates the reaction by replacing or adding to one of the CO ligands on cobalt, resulting in decarbonylation of a radical complex. In another reaction involving cobalt, oxidation of dicobalt octacarbonyl with TEMPO in the presence of oleic acid has been utilized by Pericàs to form monodisperse CoO nanoparticles (Scheme 36).⁹⁷

Scheme 36 TEMPO as an oxidant of dicobalt octacarbonyl in the formation of monodisperse CoO nanoparticles.

In general, the use of TEMPO as an oxidant in metal catalyzed or mediated reactions will be far more economical when the nitroxide can be used in small amounts. Efforts to utilize TEMPO as a catalyst, with air as the stoichiometric oxidant in metal catalyzed reactions, are being actively pursued by a number of laboratories: new advances in this arena are expected in the near future.

5.2 Oxidations via Oxoammonium Salts

5.2.1 Chemoselective Oxidation of Alcohols

Oxoammonium salts derived from nitroxides have been widely utilized in the oxidation of primary and secondary alcohols to the corresponding aldehydes, ketones, and carboxylic acids. The oxoammonium salt can be preformed and used stoichiometrically. Alternatively, it can be generated *in situ* from acid-catalyzed disproportionation of nitroxide radicals or from oxidation of a catalytic amount of nitroxide with a stoichiometric cooxidant. Since nitroxides are effective radical scavengers, potential autooxidation of the aldehyde products is inhibited.⁹⁸

There are reports of many structurally diverse oxoammonium salts⁷¹; however, most oxidations have been carried out using piperidinyl nitroxide-derived species. Oxoammonium salts can be prepared by acid-catalyzed disproportionation of nitroxides,⁹⁹ which in turn are prepared by oxidation of the corresponding hindered amines (Scheme 37). Disproportionation leads to a 1:1 mixture of the oxoammonium salt and the corresponding hydroxyammonium salt. The latter can be oxidized *in situ* by hypohalites to form the oxoammonium salt or the nitroxide radical on treatment with air. Alternatively, one-electron oxidation of nitroxide with halogen (Cl₂ or Br₂) or hypohalite gives oxoammonium cation with a halogen anion.¹⁰⁰ Use of bromine can result in bromide or tribromide as the counterion or a mixture.⁷¹ A side reaction is bromination of allylic alcohols.¹⁰⁰ Chloride as counterion can lead to unstable oxoammonium salts. Nitrogen dioxide (NO₂) has been used to make oxoammonium nitrate.⁷¹ The most common counterions are Br[−], Cl[−], Br₃[−], ClO₄[−], BF₄[−], SbF₆[−], NO₃[−],

Scheme 37 Preparation of oxoammonium salts via oxidation of the corresponding hindered amines to the nitroxides, followed by acid disproportionation.

and ClO_2^- . The only commercially available oxoammonium salt is Bobbitt and coworkers¹⁰¹ stable, nonhygroscopic *N*-acetyl-4-amino oxoammonium tetrafluoroborate ($\text{X}^- = \text{BF}_4^-$ and $\text{R} = \text{NHAc}$). The perchlorate salt ($\text{X}^- = \text{ClO}_4^-$)¹⁰² is no longer used, due to its detonation potential.¹⁰³

Since oxoammonium salts are colored, many oxidations are monitored colorimetrically. The reaction mixture usually turns from a bright yellow slurry into a white slurry.¹⁰² Another advantage of using stoichiometric oxoammonium salts is that there is no cooxidant that might decrease selectivity. Reactions in acid and base differ in their mechanisms and chemoselectivities. The rate of the oxidation increases with increasing pH of the reaction medium; thus, most oxidations were carried out under basic conditions. Under strongly acidic conditions, oxidation is slow, and secondary alcohols are favored over primary. A mechanism involving hydride transfer to the electrophilic oxoammonium oxygen (Scheme 38) was first proposed by Golubev *et al.*^{99,104} A kinetic isotope effect of $k_{\text{H}}/k_{\text{D}} = 3.1$ supports deprotonation as the rate-limiting step. A similar hydride transfer to an oxoammonium salt in the oxidative cleavage of benzyl alkyl ethers (*vide infra*) was reported recently by Bobbitt and

coworkers.¹⁰⁵ Secondary alcohols react in preference to primary alcohols because of the weaker carbon–hydrogen bond strength, making secondary alcohols better hydride donors.

Under mildly acidic or basic conditions, oxidation is rapid, and primary alcohols react preferentially over secondary alcohols. The mechanism, originally proposed by Semmelhack *et al.*,¹⁰⁶ involves the nucleophilic attack of the alcoholate on the nitrogen of the oxoammonium salt, followed by intramolecular deprotonation in an oxa-Cope fragmentation (Scheme 39).^{104,106} The slower addition of more hindered secondary alcohols to the oxoammonium species explains the preferential oxidation of primary alcohols. A kinetic isotope effect of $k_{\text{H}}/k_{\text{D}} = 1.8$ supports this mechanism.

The oxidation of alcohols with oxoammonium salts has been reviewed by Bobbitt *et al.*^{71,76}

Scheme 38 Oxidation of alcohols with oxoammonium salts under acidic conditions.

Scheme 39 Oxidation of alcohols with oxoammonium salts under basic conditions.

As an example, stoichiometric, *N*-acetyl-4-amino oxoammonium tetrafluoroborate has been used to oxidize unsaturated alcohols. In the synthesis of an insect pheromone, an ω -haloalkenol was oxidized in the presence of silica gel or pyridine in higher yield than with PCC.¹⁰⁷ However, alcohols bearing isolated dienes can suffer from acid catalyzed destruction of olefins in the presence of silica gel. The use of pyridine instead of silica gel circumvents this problem. Two equivalents of pyridine are required in the synproportionation reaction. The pyridine conditions allow oxidation of substrates bearing acid-sensitive protecting groups such as acetals and silyl ethers. Alcohols containing a β -oxygen substituent do not undergo oxidation under mildly acidic conditions due to intramolecular hydrogen bonding.¹⁰² However, they are oxidatively dimerized in the presence of pyridine to esters.¹⁰¹ Tetraethylene glycol was oxidized and cyclized to a 12-membered ring lactone with oxoammonium salts supported on a polymer surface.¹⁰⁸ Stoichiometric oxoammonium salt has been utilized in the selective oxidation of monosaccharides under basic conditions.^{109,110}

One pot oxidation of primary alcohols to the corresponding carboxylic acids using oxoammonium salts generated *in situ* from a unhindered class of nitroxides: 1-methyl-azaadamantane *N*-oxyl (1-Me-AZADO), in combination with NaClO₂ was recently reported by Iwabuchi and coworkers.¹¹¹ The oxoammonium ion reacts with the alcohol to give an aldehyde, which then reacts with NaClO₂ to give the carboxylic acid product. These reaction conditions are notable in that the reaction medium is virtually bleach-free, as the destructive NaOCl byproduct is immediately consumed by the hydroxylamine to regenerate the oxoammonium ion. As a result, carboxylic acids are obtained in good yields without competing oxidation of electron-rich alkenes and aromatic rings. In contrast, the use of the more traditional “Merck method” employing TEMPO/NaOCl/NaClO₂ failed.¹¹²

Tertiary allylic alcohols undergo an oxidative rearrangement on treatment with oxoammonium salts.¹¹³ Three possible mechanistic pathways have been purposed (Scheme 40). In the first, addition of alcohol to the oxoammonium salt forms adduct **a**, which undergoes a concerted intramolecular

Scheme 40 Three plausible reaction mechanisms for the oxidative rearrangement of tertiary allylic alcohols with oxoammonium salts.

rearrangement to form adduct **b**. Alternatively, adduct **b** can form via ionization of the allylic cation **c**. A third possibility is intermolecular S_N2' displacement by water to form allylic alcohol **d**, which can add to another oxoammonium to form intermediate **b**. Adduct **b** then fragments, presumably by deprotonation, to form the α, β -unsaturated ketone. Addition of water improves the yield in some cases. This reaction only works with oxoammonium salts consisting of bulky, nonnucleophilic counter anions (BF_4^- and SbF_6^-).

Treatment of nitroxides with relatively strong acids such as peracids or *p*-toluenesulfonic acid facilitates disproportionation to form one oxoammonium salt *in situ* for every 2 equiv of nitroxide. Since the medium must be below $pH \approx 2$, this method is not suitable for acid-labile substrates. When using *m*-chloroperbenzoic acid, hindered amines could be used directly, as they are oxidized by peracids to the nitroxides.^{114,115} Bromide and chloride ions were found to be effective as cocatalysts. The disadvantages of using peracids are partial overoxidation of the aldehyde to the carboxylic acid and competing epoxidation of double bonds. Baeyer–Villiger oxidation usually does not interfere since it is significantly slower than the nitroxide-mediated oxidation.¹¹⁶ For example, 2 equiv of nitroxide and 2 equiv of *p*-toluenesulfonic acid were used to oxidize primary and secondary alcohols to aldehydes and ketones in high yield.¹¹⁷ The resulting hydroxylamine salt can be recovered by filtration using *N*-acetyl-4-amino-TEMPO instead of the parent TEMPO. This procedure was applied to the oxidation of open-chain and cyclic *vic*-diols to form α -dicarbonyls; C–C bond cleavage was not observed.¹¹⁸ In the example depicted in Scheme 41, the nitroxide-mediated oxidation gave the diketone in 89% yield, while use of the traditional Swern reagent produced only 68% yield. Interestingly, bromotopolone was the only product obtained when 1 equiv of the preformed oxoammonium salt was used. This product arose via mono-oxidation to form an acyloin intermediate, which underwent enolization, electrocyclization, and finally dehydrobromination.

Although stoichiometric oxoammonium salts have been used successfully for the oxidation of alcohols, the ability to use the nitroxide in a catalytic manner is more attractive. A variety of organic and inorganic primary oxidants have been used to oxidize the nitroxide and to reoxidize the

Scheme 41 Oxidation of 1,2-diol to α -diketone with oxoammonium salt generated *in situ* from acid-catalyzed disproportionation versus reaction with preformed oxoammonium salt.
